ABSTRACT

USING BIO-CHARS AS POTENTIAL CATALYSTS FOR UPGRADING WOOD PYROLYSIS VAPORS

Wenjia Jin

Pyrolysis is a promising thermochemical conversion method to process lignocellulosic biomass to produce bio-oil that can be further refined into chemicals and fuels compatible with current petrochemical fuels. However, bio-oils are highly reactive and unstable and therefore must be refined immediately, thereby reducing process sustainability. Catalytic modifications of pyrolysis vapors have been researched to improve bio-oil stability. However, using traditional highly active petroleum refining cracking catalysts for catalytic pyrolysis has shown some negative results, for example, increasing bio-oil moisture content and reducing its calorific value. Therefore, this project aims at understanding decomposition behavior of wood components, its chemical constituent polymers and using moderate catalysts, like bio-chars.

Thermo-chemical decomposition behavior for wood components (bark, sapwood and heartwood) and individual wood-polymers (cellulose, hemicellulose and lignin) of typical hardwood is presented. Two hardwood species, namely red oak and yellow-poplar, were separated into their bark, sapwood and heartwood components. The samples were tested for calorific value, specific gravity, proximate analysis, mineral composition, chemical composition, ultimate analysis, and thermo-chemical decomposition behavior. In addition, the thermo-chemical decomposition behaviors of cellulose, xylan, and lignin polymers were tested. The activation energy was calculated for various fractional conversion values using the isoconversion method. The results showed that char yields from lignin, cellulose and xylan polymers were 41.43%, 4.45% and 1.89%, respectively, at the end of pyrolysis. Furthermore, cellulose, xylan and lignin polymers decomposed dramatically in the temperature ranges of 320 °C to 360 °C, 150 °C to 230 °C and 100 °C to 410 °C, respectively, with decomposition peaks at 340 °C, 200 °C and 340°C, respectively. In addition, the maximum activation energy for cellulose was 381 kJ/mol at 360 °C and for xylan it was 348 kJ/mol at 210°C.

Catalytic performance of catalysts switchgrass bio-char and red oak bark bio-char during vapor upgrading pyrolysis are documented. The clean woodchip was pyrolyzed with and without vapor upgrading under atmosphere pressure at the target temperature of 500 °C. The catalysts showed significant positive effects on the bio-oil yields, moisture content and pH value of bio-oils. However, the vapor upgrading process significantly decreased the carbon yield of bio-oil when using switchgrass bio-char as catalyst. The bio-oil yield decreased from 49.31% (no catalyst) to 44.81% (switchgrass bio-char catalyst) and to 48.68% (red oak bark bio-char catalyst). The lost mass of bio-oil ended-up in the gaseous phase as reflected in hydrogen, carbon dioxide, and carbon monoxide content. As result, at 400°C, hydrogen content increased from 0.82% to 3.74%, carbon dioxide content increased from 21.16% to 32.33%, and carbon monoxide content increased from 16.49% to 23.19% for switchgrass bio-char catalyst compared to no catalyst pyrolysis.

CHAPTER 1: INTRODUCTION

Lignocellulose biomass, such as wood, is one of the main renewable energy resources. Biomass is different from other renewable energy resources as it is the only one that can produce liquid, solid and gaseous fuels when processed through appropriate methods. The processing methods of biomass can be divided into biological (anaerobic digestion and fermentation) and thermal pathways. Thermal pathways are direct combustion, gasification and fast pyrolysis. Combustion can provide the heat and steam for later electricity generation. In addition, gasification of biomass can provide a fuel gas for combustion, electricity generation, and liquid fuel production indirectly via Fisher-Tropsch process. Fast pyrolysis is the only thermochemical method that can directly produce liquid fuel, which can substitute for fuel oil to be used for heating or electricity generation. As liquid fuel is more convenient for transportation and storage, currently more study is focusing on the fast pyrolysis (U.S. Energy Information Administration, 2012).

1.1. Pyrolysis Process

Pyrolysis reactions take place in an inert atmosphere at elevated temperatures. The processing temperature of fast pyrolysis ranges from 400 °C to 650 °C (Mohan et al., 2006). During pyrolysis, heat transfers from the heat source to the biomass feedstock raising its temperature well above the decomposition temperature of biomass polymers (cellulose, hemicellulose, lignin, etc.). Most fast pyrolysis processes are followed by catalytic upgrading of pyrolysis vapors. Kinetics and thermal decomposition mechanisms for the pyrolysis of plant biomass and its constituents have been studied extensively. Recently, more studies have focused on the use of catalysts for biomass cracking (*in-situ* upgrading and *ex-situ* upgrading) to generate chemicals (Mohan et al., 2006). Two main products are

produced during this process, condensable vapors and solid products. The condensable vapors are cooled to form a dark brown liquid, mostly referred to as bio-oil. The bio-oil yield has been reported as high as 80% of the weight of the dry biomass. The solid product is called bio-char or char and non-condensable vapors are called gaseous products (Bridgwater and Peacocke, 2000).

Pyrolysis is difficult to precisely define, especially when applied to biomass. Old literature generally equates pyrolysis to carbonization, in which the principal product is a solid char. However, now pyrolysis is defined as the processes in which bio-oils are preferred products.

The general mechanisms that occur during pyrolysis are described by Czernik et al. (1994). The mechanism involves transfer of heat from a heat source to the inner matrix of biomass followed by series of complex pyrolysis reactions at places where the temperature reaches critical pyrolysis temperature. The pyrolysis reactions lead to release of volatiles and formation of char. The volatiles are removed through carrier gas away from the reaction zones and through macro pores of the char. Some volatiles may deposit back on relatively colder biomass surfaces leading to secondary cracking reactions. The thermal cracking includes further thermal decomposition, reforming, water-gas shift reaction, radical recombination, and dehydration, which are a function of the process's residence time, temperature, and pressure profile.

1.2. Anatomy of Biomass

The properties of pyrolysis products generally depend on the type of wood, either hardwood or softwood, or biomass used. Generally, "hardwood" is a rather imprecise term identifying the broad class of angiosperm trees. "Softwood" identifies the class of

gymnosperm trees. The terms hardwood and softwood can be misleading because they have little relation to the wood hardness. Generally speaking, the microscopic cellular structure in softwood and hardwood is different. Hardwood contains longitudinal wood fibers, which provide strength and vessel elements, and conduct sap. However, softwood has only one type of cells called tracheid, which serves both purposes. The major chemical polymers of woody biomass are cellulose (40-50%), hemicellulose (25-35%) and lignin (18-35%) polymers (Rowell, 1984). All these chemical polymers simultaneously decompose during pyrolysis. In this case, biomass pyrolysis products are a complex combination of the products from the pyrolysis of individual polymer: cellulose, hemicellulose, lignin and extractives. Cellulose fibers provide wood its strength and comprise 40-50 wt. % of dry wood. Cellulose is a high molecular-weight (10^6 or more) linear polymer (Figure 1.1). The basic repeating unit of the cellulose polymer consists of two glucose anhydride units, called a cellobiose unit (Rowell, 1984).

Figure 1.1. Chemical structure of cellulose (Rowell, 1984).

The degradation of cellulose occurs between 240-350 °C. Hydrocellulose and levoglucosan are produced during the degradation reaction (Cooper, 1944; Van Hove, 1956). Tang and Neill (1964) observed that cellulose degradation were completed at 360°C at the

heating rate 12 °C/min under an atmosphere of helium. They also observed an exothermic nature of the decomposition reaction at 335°C (Tang and Neill, 1964).

Hemicellulose usually accounts for 25%-35% of the mass of dry wood. It is the second major chemical constituent in wood. However, its content varies from one wood species to another. Generally, hemicellulose content is 28% in softwoods, and 35% in hardwoods (Rowell, 1984). Hemicellulose is a mixture of various polymerized monosaccharides, including glucose, mannose, galactose, xylose, arabinose, 4-O-methyl glucuronic acid and galacturonic acid residues (Figure 1.2) (Egüés et al., 2013). Hardwood hemicelluloses are rich in xylan and contain small amounts of glucomannan. In addition, softwood hemicelluloses contain a small amount of xylan but are rich in galactoglucomannan (Han et al. 2013).

Figure 1.2. Main types of hemicellulose (Mohan et al., 2006)

The degradation of hemicellulose takes place in the temperatures range of 200-260 °C. Hemicellulose pyrolysis produces more volatiles, less tars, and less chars than cellulose pyrolysis. Most hemicelluloses do not yield significant amounts of levoglucosan.

Lignin is the third major polymer of wood, which accounts for 25%-35% of the weight of softwoods and 16%-25% of the weight of hardwoods (Rowell, 1984). Lignin acts as a binder for the agglomeration of fibrous cellulosic components. Also, it protects cellulosic fibers from rapid microbial and fungal destruction. Lignin is a three-dimensional, amorphous, highly branched, polyphenolic unit (Figure 1.3) (Joseph and Aminul, 1999). Lignin mainly decomposes in a temperature range of 280 to 500 °C. The main products of lignin pyrolysis are phenols. Lignin is more difficult to degrade than cellulose or hemicelluloses. In addition, lignin pyrolysis produces more residual char than does the pyrolysis of cellulose (Zhang et al., 2012b).

1.3. Pyrolysis Products

Bio-oil is combination of pyrolysis products of cellulose, hemicellulose, and lignin polymers. Bio-oil from fast pyrolysis has several environmental advantages over fossil fuels (Mohan et al., 2006). First of all, bio-oils may be considered carbon neutral, but this is still under debate. In this case, they may generate carbon dioxide credits. Also, woody biomass contains insignificant amounts of sulfur. Therefore, no SO_x emissions are generated. Bio-oil fuels also generate more than 50% lower NO_x emissions than traditional fossil fuel. Therefore, bio-fuels are cleaner and cause less pollution (Pütin, 2002).

Figure 1.3. p-Coumaryl, coniferyl, and sinapyl structures and resonance hybrid structures of phenoxyl radicals produced by the oxidation of coniferyl (Mohan et al., 2006)

The yield of bio-oils from wood and other biomass is in the range of 60 – 95 wt.% (Bridgwater, 1996). The appearance of bio-oil is almost black or dark red-brown to dark green, depending on the initial feedstock and the mode of fast pyrolysis. The bio-oil has varying quantities of water content, ranging from 30 to 50 wt. %, depending on the production and collection method. In addition, bio-oil cannot be dissolved in water. The bio-oil density is higher (1.2 kg/L) than light fuel oils (0.85 kg/L)(Bridgwater and Peacocke, 2000). The viscosity of bio-oil varies from as low as 25 cSt to as high as 1000 cSt (measured at 40 °C) depending on the feedstock, the water content of the oil, the pyrolysis process used, and the extent to which the oil has been aged. The aging of bio-oil causes an increase in viscosity and a decrease in volatility, phase separation, and change in deposition of gums with time (Bridgwater and Peacocke, 2000). Bio-oil can serve as a substitute for fuel oil or diesel in many static applications, including boilers, furnaces, engines, and turbines for electricity generation (Shihadeh and Hochgreb, 2000). A surface-active bio-oil solution, that

was prepared from vacuum pyrolysis bio-oil with a phenol-to-levoglucosan mass ratio of 4.8, was used as a foaming agent in the flotation of sulfured copper (Bridgwater, 1996).

1.4. Catalytic Pyrolysis

Bio-oil from the pyrolysis process needs further refining before it can be directly used as gasoline. In principle, bio-oil is refined using petroleum refining technology, which has two stages in processing: hydrotreating and hydrocracking. Butane or lighter components, stable hydrogenated oils, and a heavy fraction (boiling point $> 350\text{ }^{\circ}\text{C}$) are formed during the first stage of hydrotreatment (Jones, 2009). The hydrogenated oils formed in first stage are separated from the other fractions by distillation, and the remaining heavy fraction is hydrocracked into light hydrocarbon diesel fuels in the second stage. The resulting hydrogenated oils are stable enough to be used as gasoline, with a much higher-energy content ($\text{HHV} = 46\text{ MJ/kg}$) (Jones et al., 2009). In petroleum-refining processes, Fluid Catalytic Cracking (FCC) catalysts, hydrocracking catalysts, and hydrotreating catalysts are employed (Gerber, 1999). During the pyrolysis process, the catalysts transform heavy crude oil into light high-quality oil fractions. However, the two-stage process suffers from catalyst life and performance. The performance properties of industrial catalysts (FCC, ZSM-5 and metal oxidized ZSM-5) are shown in Table 1.1. A literature review shows that all FCC and ZSM catalysts prefer to gasify products produced from cellulose and hemicellulose pyrolysis than products produced from lignin. It is well documented that using the above catalysts decreases net carbon yield and increases moisture content of bio-oil (French and Czernik, 2010).

Table 1.1 Performance of petroleum industry catalysts (FCC, ZSM-5 and metal oxidized ZSM-5).

Catalyst	Structure	Functions in petroleum industry	Drawbacks when used as woody biomass pyrolysis catalyst
Fluid Catalytic Cracking	Made up of finely divided (~1-5 μm) lanthanide-89 substituted X-or Y-type zeolite imbedded in amorphous silica-alumina particles (~50 μm).	Increase yield of gasoline from heavy gas oils, naphtha, and some residual oil.	Deactivates very quickly due to coke deposition and requires constant regeneration. Metals in feedstock poison FCC catalysts. Less bio-oil yield, increased coke and gas yields(Zhang et al., 2012a).
ZSM-5	contains a microporous crystalline structure containing oxides of Si and Al (Derouane et al, 1981) in form of AlO_4 and SiO_4	Formation Si-OH groups at the catalyst surface at 600°C can provide reactive acid-base sites to catalyst.	Coke formed at acid-base sites leads to deactivation of these sites. Less acid and alcohols, and more ketones formed during the pyrolysis process (Aho et al., 2008) Low bio-oil yield and less average molecular weight obtained (Williams and Nugranad, 2000). Increased moisture content in bio-oil from 5.4% to 16.7% (Aho et al. 2008)
Metal-oxide ZSM-5	Metal oxide species (MO_x) are impregnated on the porous structure of the ZSM-5 (Lee and Wachs, 2008)	Metal oxides attach themselves to the acid sites of the zeolite surface and form double –bonded oxygen function groups. The heavy organic compounds first interact with alumina site and create unstable organic radicals (Lee and Wachs, 2008).	Ni loaded ZSM-5 leads to the formation of toluene (French and Czernik, 2010).

A solution to reducing negative effects of petroleum refining catalysts would be to use bio-char catalysts. Bio-chars are not being used as a catalyst during the pyrolysis process. However, it has a highly porous structure with great surface area and sorption properties, comparable silica-to-alumina ratio, making bio-chars potential catalysts for the pyrolysis process. Two main approaches have been adopted to incorporate catalysts during pyrolysis. The first approach is to mix the catalyst with the feedstock during pyrolysis; the other approach is to perform vapor upgrading using catalysts before the products are condensed.

1.5. Objectives

Therefore, this study is aimed at conducting pyrolysis kinetics of wood polymers and exploring the use of bio-char as a potential catalyst for pyrolysis vapor refining. The objectives of this study were follows:

1.To document the thermo-chemical decomposition behavior of hardwood's physical components and to model the decomposition of wood polymers (cellulose, hemicellulose (xylan) and lignin polymers) using thermo-gravimetric analysis and the isoconversion method.

2.To compare the influence of bio-char catalysis on *ex-situ* pyrolysis vapor upgrading during woodchip pyrolysis.

This study first explores the pyrolysis kinetics of different wood polymers (cellulose, hemicellulose and lignin) and wood physical components (bark, sapwood and heartwood). Additionally, switchgrass bio-char and red oak bark bio-char are used as the catalyst during vapor upgrading of pyrolysis products.

CHAPTER 2: PYROLYSIS KINETICS OF PHYSICAL COMPONENTS OF WOOD AND WOOD-POLYMERS USING ISOCONVERSION METHOD

2.1. Introduction

Renewable energy is currently attracting worldwide interest, as it is partly the solution to environmental concerns arising from the overuse of fossil fuels. Consumption of traditional fossil fuels releases carbon stored beneath the earth's crust for millennia into the atmosphere in the form of greenhouse gases (GHG) which are responsible for global warming. On the other hand, biomass when burned as fuel releases carbon previously sequestered from the atmosphere, thereby, theoretically not increasing GHG levels. The GHG emissions during the combustion of biomass are assumed to be the same as that absorbed through the photosynthesis process during biomass growth (Demirbas, 2005), especially in the case of forest and agricultural biomass (Biagini et al., 2006). However, an overall life cycle analysis has shown an increase in GHG emissions for biomass utilization for biofuels (International, 2009). The increased GHG emissions are the result of the use of fossil energy during various operations involved in supply-chain logistics, for example, harvesting, transport, preprocessing, and inefficient conversion technologies (Nitschke and Innes, 2008). On the other hand Sharma et al. (Sharma and Rowe, 1992) reported that biomass collection from prolonged sustainably managed forests actually reduces net GHG emissions, thereby, making it carbon negative. In the United States, the total primary energy consumption from various biomass resources is currently 4%, and it is expected to increase to 10% by the year 2035 (EIA, 2012). Most of the biomass utilization for bioenergy accounts for generation of electricity, heat and liquid transportation fuels. Among this biomass feedstock, roughly, more than 50% is in the form of woody biomass (Stokes,

2011). The current contribution of woody biomass is 130 million dry tons, and it is expected reach to 210 and 225 million dry tons by 2022 and 2030, respectively (Stokes, 2011). Woody biomass is mainly used for electricity production, heating homes and providing process heat for industrial facilities through three primary thermal-conversion methods—combustion, gasification and pyrolysis (Balat, 2006; Demirbaş, 2001; McKendry, 2002; Panwar et al., 2012). The process air requirements vary for these three thermal-conversion methods. For combustion, gasification and pyrolysis the air consumption is excess, partial and nonexistent, respectively (Balat et al., 2009).

Pyrolysis is inherently present in combustion and gasification processes. It is an outstanding conversion method as it can directly generate solid, liquid and gaseous products under anoxic conditions (Balat et al., 2009). The wood polymers (cellulose, hemicellulose and lignin) present in any biomass and the pyrolytic conditions are the primary factors that control pyrolysis reactions and resulting products (Raveendran et al., 1996). Any typical woody biomass contains 40-50% cellulose, 25-35% hemicellulose and 10%-40% lignin (Mohan et al., 2006; Yaman, 2004). In addition, the pyrolytic conditions including pyrolysis temperature, pyrolysis pressure, vapor-phase residence time and heating rate affect the chemical reactions responsible for producing various chemical compounds present in bio-oils (Antal, 2004).

Wood polymers of woody biomass (cellulose, hemicellulose and lignin) interact during pyrolysis. In the temperature range of 150 °C to 180 °C, the stability of cellulose is reduced (Beall and Eickner, 1970). Furthermore, residual cellulose is protected by lignin after the temperature reaches 300 °C (Beall and Eickner, 1970). In previous studies data on weight loss as a function of temperature was generated from TGA (Thermogravimetric

analysis) equipment to study pyrolysis kinetics of woody biomass (Gaur, 1998). Different experimental methods and mathematical models have been used to carry out the TGA experiments. For example, the isothermal method uses constant temperatures while non-isothermal heating ramps the temperature from ambient to the target temperature at a given heating rate. The data generated from TGA include temperature, time and weight changes during the pyrolysis process and these data can be used to calculate the activation energies of different pyrolysis phases (Mohan et al., 2006) using a variety of mathematical models.

Activation energy, a quantified factor of pyrolysis kinetics has been studied by several different mathematical methods (Gaur, 1998). Gaur and Reed (Gaur, 1998) have documented the following methods for TGA data processing: Coat and Redfern method-1964; Gyulai and Greenhow method-1974; Doyle's method-1961; Zsako method-1973; Satava and Skvara method-1969; Freeman and Carroll method-1958; Ingraham and Marrier method; Vachuska and Voboril method; Varhegyi's Integral Solution-1978; and Gaur and Reed method-1994.

While determination of pyrolysis kinetics is critical to the understanding of the pyrolysis process for a given biomass, only a handful of studies have reported hardwood kinetics (Herrera et al., 1986; Slopicka et al., 2012). However, no study has documented the effects of physical components (sapwood, heartwood and bark) during the pyrolysis process. The wood polymers in sapwood, heartwood and lignin are expected to be different and, in this case, may lead to different pyrolysis results.

This paper presents the thermo-chemical decomposition behavior of hardwood's physical components and model wood-polymers—cellulose, hemicellulose (xylan) and lignin polymers—using thermo-gravimetric analysis and the isoconversion method. The use

of the isoconversion method has been successfully documented for pyrolysis kinetics (Kim et al., 2005; Kim and Kim, 2004). It was hypothesized that pyrolysis kinetics of sapwood, heartwood, and bark will be different and that the isoconversion method will be valid for estimation of Arrhenius parameters for all fractional conversion values.

2.2. Experiment Procedures

Fresh samples of yellow-poplar and red oak were collected from the West Virginia University (WVU) Research Forest. The samples were separated into twelve sub-samples of bark, sapwood and heartwood (Figure 2.1). The physical components (bark, sapwood and heartwood) were ground to less than 1 mm particle size using a mill (Model: ED5, Thomas, Chillicothe, MO), and subsequently oven dried for 24 hours at 103 °C. In addition, pure cellulose (9004-34-6, Fisher, Hanover Park, IL), xylan (58-86-6, TCI, Portland, OR) and lignin (Indulin AT, Meadwestvaco, Charleston, SC) were obtained from commercial vendors as representative of wood-polymers. All samples were analyzed for the cell-wall specific gravity, calorific value, ultimate analysis (carbon, hydrogen, nitrogen, and sulfur content), proximate analysis (fixed carbon, volatile matter, and ash content) and thermo-chemical decomposition behavior. In addition, the wood samples were tested for mineral composition and chemical composition by the Agricultural and Environmental Sciences Laboratory, University of Georgia.

Specific gravity (true grind density) was measured according to ASAE Standard S269.4 using a Multipycnometer (Model: Manual Multipycnometer, Quantachrome, FL). Calorific value was measured using a bomb calorimeter (Model: 6300 Calorimeter, Parr Instrument Company, IL) according to the ASTM D5865 standard without accounting for

heat of reactions for nitric and sulfuric acids. Ultimate analysis was performed using a CHNS analysis (Model: Series II CNHS/O Analyzer 2400, PerkinElmer, Waltham, MA). Proximate analysis (moisture, volatile matter, fixed carbon and ash) was carried out using a proximate analyzer (Model: LECO 701, LECO Corporation, St. Joseph, MI) following the ASTM D3174 standard. Mineral composition, Acid Detergent Fiber (ADF), Neutral Detergent Fiber (NDF), and Acid Detergent Lignin (ADL) were measured at the University of Georgia Agricultural and Environmental Sciences Lab, Athens (UGA-AESL), GA. Data on fiber analysis and ash content were used to determine cellulose, hemicellulose, and lignin content according to following equations:

$$\% \text{Hemicellulose} = \% \text{NDF} - \% \text{ADF}$$

$$\% \text{Cellulose} = \% \text{ADF} - (\% \text{Lignin} + \% \text{Ash}).$$

Figure 2.1. Yellow-poplar and red oak samples showing bark, sapwood and heartwood.

Thermo-chemical decomposition behavior was assessed using a thermogravimetric analyzer (TGA) (Model: Q50, TA Instruments, Schaumburg, IL). The TGA

experiments were performed by heating a 8-12 mg sample from 50 °C to 700 °C at three heating rates of 10 °C, 30 °C, and 50 °C/min under a nitrogen flow of 50 cm³/min. Data obtained from thermo-gravimetric analysis were analyzed for any changes in thermo-chemical decomposition behavior. The TGA data were analyzed to determine the Arrhenius activation energy (E) and pre-exponential constant (A) using the isoconversion method described by Kim et al. (Kim and Agblevor, 2007). In this method, the rate of fractional weight loss, dX/dt, is expressed as a function of conversion $f(X) = (1-X)^n$, where X is fractional conversion $\left(\frac{\text{initial weight}-\text{current weight}}{\text{initial weight}-\text{final weight}}\right)$ and 'n' is the order of the reaction:

$$\frac{dX}{dt} = k.(1 - X)^n \quad (2 - 1)$$

The reaction rate constant (k) was substituted by the following Arrhenius expression:

$$k = A.\exp\left(-\frac{E}{RT}\right) \quad (2 - 2)$$

Where R is universal gas constant and T is the absolute temperature in K. Upon substituting equation (2) into equation (1) and taking the natural logarithm, equation (1) is transformed into the following equation:

$$\ln\left(\frac{dX}{dt}\right) = \ln A + n \ln(1 - X) - \frac{E}{RT} \quad (2 - 3)$$

The activation energy (E) in equation (3) was determined from the relationship between $\ln(dX/dt)$ and $(1/T)$ for fractional weight loss (X). Consequently, a family of graphical curves was obtained for a series of X (0.01, 0.02..., 0.9) values of fractional

conversion. For example, the corresponding temperatures at 0.5 conversion of the cellulose samples were 608.15, 622.15, and 628.15K, respectively, for the heating rates 10, 30, and 50 °C/min. The values of $\ln(dX/dt)$ were: -1.3451, -0.41228, and -0.09330, with corresponding $1/T$ values of 1.644331×10^{-3} , 1.607329×10^{-3} , 1.591976×10^{-3} (K^{-1}). The intercept ($\ln(A(1-X)^n)$) was calculated from the linear relationship for the corresponding conversions assuming the order of reaction to be either 0 or 1.

2.3. Results and Discussion

2.3.1. Feedstock Characterization

Thermogravimetric Analysis

Physical and chemical properties including calorific value, cell wall specific gravity, ultimate analysis, proximate analysis, mineral analysis of woody biomass physical components (bark, sapwood and heartwood) and wood polymers (cellulose, xylan and lignin) were determined as references for further analysis. Table 2.1 shows the results of cell-wall specific gravity and calorific values for all samples. As shown in Table 2.1, there are no significant differences among the cell-wall specific gravity of bark, sapwood and heartwood samples of red oak and yellow-poplar ($p\text{-value} > 0.05$). Similar results were observed for the calorific value data which were consistent with Corder's findings (Corder, 1976). Adebayo et al. (Adebayo et al., 2009) had measured specific gravity of wooden blocks of size 10×10×40mm of sapwood and heartwood of red oak and yellow-poplar samples. The reported average overall specific gravity of sapwood and heartwood logs (not of cell-wall) were 0.46 and 0.46 for red oak, and 0.58 and 0.61 for yellow-poplar, respectively (Adebayo et al., 2009). The cell-wall specific gravity, reported in this paper, is

always greater than that of wood because it does not account for pores present. The result was in agreement with a previous study (Vincent, 1999). The difference between the overall specific gravity and cell-wall specific gravity is related to the porosity of the wood matrix. Porosity directly affects heat transfer and mass transfer during biomass pyrolysis (Miller and Bellan, 1996). Miller and Bellan (1996) have reported that high initial porosity reduced heat transfer rates during pyrolysis. However, given small sample size (10-12mg) in the present thermogravimetric experiments, it is unlikely that heat and mass transfer limitation effects would be observed.

Table 2.1. Calorific value and cell wall specific gravity measurements (mean $\pm$ standard deviation, 2 replications, 2 measurements on each replication) for samples of yellow-poplar and red oak's components (bark, sapwood and heartwood) and wood-polymers.

Property		Calorific value (MJ/Kg)	Cell wall specific gravity
Red oak	Bark	18.86 $\pm$ 0.44	1.69 $\pm$ 0.07
	Sapwood	18.78 $\pm$ 0.51	1.85 $\pm$ 0.18
	Heartwood	18.38 $\pm$ 0.36	1.79 $\pm$ 0.12
Yellow-poplar	Bark	19.54 $\pm$ 1.02	1.74 $\pm$ 0.16
	Sapwood	18.81 $\pm$ 0.88	1.85 $\pm$ 0.14
	Heartwood	18.65 $\pm$ 0.86	1.92 $\pm$ 0.25
Wood polymers	Cellulose	-*	1.27
	Xylan	-*	1.53
	Lignin	25.79 $\pm$ 0.09	1.25

Table 2.2 shows the results of the ultimate analysis. No substantial differences were observed for carbon, hydrogen, and sulfur contents among bark, sapwood and heartwood. The average carbon content was 46-48%, hydrogen content was 6%, and sulfur content was 0.2%. The nitrogen content was the highest for bark followed by sapwood and

then heartwood. In addition, the carbon and sulfur content in the lignin polymer was significantly higher than in the cellulose and xylan polymers ($p < 0.05$). The significantly higher sulfur content in the lignin polymer may be explained by the pulping and rough purifying process by which it was extracted. During one pulping process, superfluous sulfur compounds are used as chemical additives (Fengel and Wegener, 2003). Additionally, when looking at the molar ratio for cellulose, it had 1.78 mols of hydrogen and 0.89 mols of oxygen for each mol of carbon. Therefore, its molar formula may be written as $C_1H_{1.78}O_{0.89}$, after ignoring nitrogen and sulfur. Similarly, molar formulae for xylan and lignin may be written as $C_1H_{1.99}O_{0.97}$ and $C_1H_{1.14}O_{0.33}$, respectively. Therefore, lignin contains the least amount of hydrogen and oxygen per mol of carbon. Similarly, molar formulae calculated for yellow-poplar sapwood, heartwood, and bark were $C_1H_{1.52}O_{0.73}$, $C_1H_{1.50}O_{0.72}$, and $C_1H_{1.48}O_{0.67}$, respectively. Bark contains less oxygen and hydrogen than sapwood and heartwood and hence it should decompose at high temperatures producing more bio-char and phenolic rich bio-oil than the other two components.

Ultimate analysis is also directly related to the higher heating value of the material (Wright et al., 2010; Xu and Lad, 2007). The Dulong formula ($HHV = 0.338C + 1.428(H - O/8) + 0.095S$) has been widely used for calculating higher heating values using C, H, and O content of biomass; however, the high ash content of biomass may limit the applicability of this formula.

Table 2.2. Ultimate analysis (carbon, hydrogen, nitrogen and sulfur content) of bark, sapwood, and heartwood of red oak and yellow-poplar and wood-polymers (cellulose, xylan and lignin).

Property		Carbon (%)	Hydrogen (%)	Nitrogen (%)	Sulfur (%)
Red oak	Bark	47.52 ± 1.44	5.86 ± 0.25	0.56 ± 0.00	0.24 ± 0.02
	Sapwood	46.62 ± 0.08	5.89 ± 0.01	0.26 ± 0.01	0.18 ± 0.04
	Heartwood	46.97 ± 0.21	5.87 ± 0.01	0.07 ± 0.01	0.16 ± 0.01
Yellow-poplar	Bark	48.16 ± 0.50	5.93 ± 0.04	0.76 ± 0.02	0.18 ± 0.06
	Sapwood	47.05 ± 0.06	5.96 ± 0.01	0.21 ± 0.03	0.21 ± 0.01
	Heartwood	47.53 ± 0.30	5.93 ± 0.06	0.13 ± 0.01	0.21 ± 0.01
Wood polymers	Cellulose	42.00 ± 0.04	6.24 ± 0.06	0.99 ± 0.07	0.67 ± 0.04
	Xylan	40.14 ± 0.42	6.65 ± 0.04	0.51 ± 0.09	0.64 ± 0.00
	Lignin	61.68 ± 0.01	5.85 ± 0.02	1.29 ± 0.10	2.06 ± 0.02

Table 2.3 shows the results of the mineral composition of the physical components (sapwood, heartwood and bark) of red oak and yellow-poplar. The phosphorus, potassium, calcium, magnesium, manganese, aluminum, zinc compositions in bark were higher than in sapwood and heartwood in both red oak and yellow-poplar. The mineral compositions in sapwood and heartwood are approximately same. Minerals present in biomass ash play a key role in catalyzing pyrolysis reactions (Raveendran et al., 1995; Yang et al., 2006). Raveendran et al. reported that cations, for example potassium and sodium, are responsible for accelerated catalytic decomposition of cellulose and hemicelluloses. Data presented in Table 2.3 show that a considerable amount of sodium and potassium is present in bark, sapwood, and heartwood of both red oak and yellow-poplar. Therefore, there may not be any observable differences in thermal decompositions of samples due to catalysis because all the samples would be catalyzed equally. Ren et al. (2009) observed enhanced conversion

of nitrogen present in biomass to NH_3 , HCN , NO , and HCNO at low temperatures when biomass was treated with KOH and CaO . Therefore, addition of minerals is desirable for fast thermal degradation of biomass but it is not recommended for nitrogen rich biomass to avoid unnecessary nitrogen loss.

Table2.3. Mineral composition in parts per million (ppm) of the physical components (sapwood, heartwood, bark) of red oak and yellow-poplar.

Sample	Red oak			Yellow-poplar		
	Bark	Sapwood	Heartwood	Bark	Sapwood	Heartwood
Phosphorus	408	127	<60	257	<60	<60
Potassium	3282	1875	684	1977	798	826
Calcium	11670	450	63	8530	482	1016
Magnesium	601	536	241	668	319	429
Manganese	1690	309	93	1415	272	364
Iron	109	107	54	105	56	51
Aluminum	78	14	5	248	22	19
Copper	2.9	2.6	1.8	5.6	1.7	1.5
Zinc	13.3	5.2	6.3	13.0	5.4	5.1
Sodium	40	18	58	23	34	19

In the proximate analysis, the average fixed carbon and volatile matter contents in bark, sapwood and heartwood of yellow-poplar and red oak were around 20% and 80%, respectively (Table 2.4). This result agrees with previous studies (Adebayo, 2010; Demirbaş, 1997). The ash content in bark (2% to 3%) was significant higher than in sapwood and heartwood (around 0.4%), ($p < 0.01$). Also, the ash and fixed carbon contents in lignin polymer were significantly higher than in cellulose and xylan polymers, and the volatile matter in lignin polymer was significantly lower than in the cellulose and xylan polymers ($p < 0.01$). The fixed carbon content of xylan (around 1.66%) was significantly lower than in cellulose (12.56%) and lignin (36.71%), ($p < 0.01$). The proximate analysis provides vital information about how biomass is expected to behave during pyrolysis. The

volatile matter content is related to the amount of biomass, excluding water, which can be volatilized by the application of heat. During pyrolysis, these volatiles end-up in either gaseous products or bio-oils. However, proximate analysis provides no information as to where the volatile matter of biomass will end-up, i.e., in the bio-oil or gases. In addition, the fixed carbon represents the ash-free carbon residue left after pyrolysis. In the absence of mass transfer limitations in large batch pyrolysis experiments, quantities of bio-char produced from pyrolysis should be theoretically equal to the sum of fixed carbon content and ash content measured from proximate analysis. However, in practical situations, actual maximum bio-char yield on an-ash free basis were reported to be 57 % (chestnut wood) and 80% (oak wood) of their respective fixed carbon contents (Antal, 2004).

Table 2.4. Proximate analysis (moisture, ash, volatile and fixed carbon (% d.b)) of bark, sapwood, and heartwood of red oak and yellow-poplar and wood-polymers (cellulose, xylan and lignin).

Property		Moisture (%)	Ash (%)	Volatile (%)	Fixed Carbon (%)
Red oak	Bark	6.94 ± 0.06	3.08 ± 0.52	77.50 ± 1.20	19.43 ± 1.73
	Sapwood	0.42 ± 0.01	0.36 ± 0.00	81.58 ± 0.02	18.07 ± 0.02
	Heartwood	6.16 ± 0.04	0.13 ± 0.01	81.84 ± 0.08	18.05 ± 0.09
Yellow-poplar	Bark	7.53 ± 0.04	2.24 ± 0.04	77.22 ± 0.17	20.55 ± 0.13
	Sapwood	6.76 ± 0.00	0.48 ± 0.02	83.53 ± 0.20	16.00 ± 0.22
	Heartwood	6.75 ± 0.01	0.50 ± 0.02	83.60 ± 0.21	15.91 ± 0.19
Wood polymers	Cellulose	5.29 ± 0.00	0.00 ± 0.05	87.47 ± 0.17	12.56 ± 0.12
	Xylan	0.00 ± 0.01	0.00 ± 0.00	98.38 ± 0.12	1.66 ± 0.13
	Lignin	3.03 ± 0.01	2.19 ± 0.08	61.10 ± 0.28	36.71 ± 0.37

The contents of cellulose, hemicellulose and lignin in red oak and yellow-poplar are presented in Table 2.5 and Figure 2.2. Lignin content in bark (around 18 to 20%) was

relatively higher than in sapwood and heartwood (in the range of 10% to 15%). In contrast, cellulose and hemicellulose contents in red oak bark (around 30% and 20%, respectively) were relatively lower than in sapwood and heartwood (around 50% and 26%, respectively). Cellulose, hemicellulose and lignin contents in sapwood and heartwood were approximately similar. Similarly, Usia et al. reported that the cellulose contents in sapwood, heartwood and bark of oak were 53.11%, 48.61% and 26.29%, respectively, and the lignin contents in three components were 28.71%, 24.14% and 33.14%, respectively (Usia and Kara, 1997). In Schowalter's report, the concentration of cellulose in oak was 0.52 (g g^{-1}) in sapwood, 0.46 (g g^{-1}) in heartwood, 0.31 (g g^{-1}) in inner bark and 0.18 (g g^{-1}) in outer bark (Schowalter et al., 1998). Percent of biomass reported in 'others' category in Table 2.5 and Figure 2.2 are lumped quantities of fat, protein, extractives, pectin etc, which were not individually measured.

Figure 2.2. Percent cellulose, hemicellulose and lignin contents (d.b.) in bark, sapwood and heartwood of red oak and yellow-poplar samples.

Table 2.5. Percent cellulose, hemicellulose and lignin contents (d.b.) in bark, sapwood and heartwood of red oak and yellow-poplar samples.

Property		Cellulose (%)	Hemicellulose (%)	Lignin (%)	Others (%)
Red oak	Bark	30.02	20.45	19.58	26.87
	Sapwood	50.87	26.86	13.38	8.52
	Heartwood	49.82	26.90	15.97	7.18
Yellow-poplar	Bark	31.54	16.73	17.98	31.82
	Sapwood	55.07	26.46	10.17	7.83
	Heartwood	54.08	25.74	11.61	8.07

Cellulose, hemicellulose and lignin are the main organic polymers that decompose during pyrolysis (Jeon et al., 2012; Liu et al., 2011; Qu et al., 2011; Raveendran et al., 1996; Yang et al., 2007; Yang et al., 2006). Each polymer behaves distinctly during pyrolysis. Cellulose degrades at 240-350 °C producing anhydrocellulose and levoglucosan. The latter is produced when a glucosan radical forms, and it does not get a chance to bridge with oxygen present in the cellulose polymer. The in-depth chemistry of this reaction is presented by Mohan et al. (2006). Unlike cellulose, which has only glucose in its chain structure, hemicellulose contains heteropolysaccharide and thermally degrades in the temperature range of 130-194 °C (Mohan et al., 2006). The differences in thermal decomposition chemistry of hemicellulose and cellulose are not well-known. The thermal decomposition of lignin occurs at 280 to 500 °C yielding phenol via cleavage of ether and carbon-carbon linkages. According to Mohan et al. lignin produces more residual char than cellulose or hemicellulose (Mohan et al., 2006). The liquid component of lignin pyrolysis is composed of menthol, acetic acid, acetone, and water; and the gaseous component is mainly methane,

ethane, and carbon-monoxide. Qu et al. reported that bio-oil yields were 65% from cellulose pyrolysis, 53% from xylan pyrolysis, and 40% from lignin pyrolysis (Qu et al., 2011). Both Raveendran et al. and Qu et al. showed that the three biomass polymers decompose independently without interfering with each other (Qu et al., 2011; Raveendran et al., 1996).

2.3.2. Thermo-Chemical Decomposition Behavior of Cellulose, Xylan, and Lignin

Figure 2.3 shows the TGA and Differential Thermogravimetric (DTG) graphics of cellulose, xylan and lignin heated from 50 °C to 700 °C at the heating rate of 10 °C/min under an inert atmosphere. The DTG curves present the rate of fractional conversion and the TGA curves show the percentage weight remaining over the temperature range. As shown in the TGA graphic (Figure 2.3a), cellulose produced 4.45% char, xylan produced 1.89% char and lignin produced 41.43% char when heated to 700 °C. The char yields should match with the sum of fixed carbon and ash content measured from proximate analysis. Similar results of lignin and cellulose char yields were presented earlier (Raveendran et al., 1996; Yang et al., 2005). The reported char yields from cellulose pyrolysis are 2.5% for Whatman cellulose, 14.0% for wood cellulose (Raveendran et al., 1996), and 7% for a fibrous powder form of cellulose (Yang et al., 2006). Similarly, char yield reported for hemicellulose is 20% for xylan extracted from birchwood (Yang et al., 2006) and 30% for xylan (Raveendran et al., 1996). The reported char yield for lignin is 40.6% for alkali lignin, 47.1% for acid lignin (Raveendran et al., 1996) and 40% for alkali lignin in brown powder form (Yang et al., 2006). Raveendran et al. reported that cellulose present in different biomass differs due to its varying crystallinity (Raveendran et al., 1996), which not only affects the char yield but also the thermal degradation behavior. Char produced from xylan was lower than that reported in

the literature. This difference is attributed to the dissimilar variety of xylan resulting in different structural and chemical properties.

When looking at the DTG graphics, cellulose decomposed dramatically in the temperature range of 300 °C to 400 °C with a large decomposition peak at 340 °C. Xylan decomposed in the temperature range of 150 °C to 400 °C with a large decomposition peak at 200 °C. Degradation of lignin occurred in the temperature range of 100 °C to 700 °C with a tiny degradation peak at 340 °C (Figure 2.3b). Similar results for lignin and cellulose degradation temperature range and peak location were presented in the literature (Raveendran et al., 1996; Yang et al., 2005). However, the large peak for xylan degradation was reported at 260 °C (Yang et al., 2005) and 300 °C (Raveendran et al., 1996). Furthermore, the reported decomposition temperature range for xylan was between 200 °C to 350 °C (Raveendran et al., 1996; Yang et al., 2005). Different results may be caused by a dissimilar variety of xylan and TGA test conditions. Yang et al. used xylan from birchwood (Sigma-Aldrich Ghemie GmbH). Raveendran et al. heated xylan from room temperature to 1000 °C at the heating rate of 50 °C/min under an inert atmosphere.

Different thermal degradation behavior of cellulose, hemi-cellulose, and lignin is attributed to their individual chemical natures (Yang et al., 2006). Among the three polymers, hemicellulose (xylan) has random amorphous structures with reactive acetyl groups that are easily broken down during acid hydrolysis. An average polymer of hemicellulose contains only 150 monomers of repeating saccharides. Unlike cellulose, which has only glucose in its chain structure, hemicellulose contains heteropolysaccharide and thermally degrades in the temperature range of 130-194°C (Mohan et al., 2006). In contrast, cellulose is a linear polymer of glucose (5000-10000 glucose units). The cellulose

degrades at 240-350°C producing anhydrocellulose and levoglucosan (Mohan et al., 2006). Cellulose polymer contains some crystalline and some amorphous regions. The crystalline regions are resistant to acid hydrolysis or solvent penetration. Ligninic polymers are highly branched, substituted, mononuclear aromatic polymers forming a lignocellulosic complex in the biomass, and this amorphous structure of lignin accounts for 16 to 33% of the mass of woody biomass (Mohan et al., 2006). The thermal decomposition of lignin occurs at 280 to 500°C yielding phenol via cleavage of ether and carbon-carbon linkages.

Figure 2.3. Thermo-gravimetric analysis results showing (a) TGA-percentage weight remaining, and (b) DTG-rate of fractional changes when samples of cellulose, xylan and lignin are heated from 50°C to 700°C at the heating rate of 10°C/min under an inert atmosphere.

Activation Energy Analysis

Figure 2.4 shows the activation energy and dX/dt curves of cellulose, xylan and lignin as a function of fractional conversion from 0.01 to 0.9. Valid activation energy values of cellulose, xylan and lignin were calculated in the fractional conversion range of 0.01 to 0.9, 0.01 to 0.4 and 0.01 to 0.5, respectively (Figure 2.4). The activation energy values in the fractional conversion range of 0.5 to 0.9 and 0.6 to 0.9 for xylan and lignin are not reported here due to their negative numerical values. The negative values could be the result of following three reasons: (1) the isoconversion model is not valid for certain fractional

conversion values, (2) the Arrhenius law is may not be applied to certain fractional conversion values, (3) overlapping multiple reactions are taking place. Therefore, the authors state that the isoconversion model does not appear to be appropriate for every value of fractional conversion.

As shown in Figure 2.4a, the activation energy of cellulose ranged from 208 kJ/mol to 381 kJ/mol for the fractional conversions range of 0.2 to 0.9, which corresponds to the temperature range of 320 °C to 360 °C. A similar result for the cellulose activation energy (242 kJ/mol) was presented by Bradbury et al. (1979) using an isothermal method. (Chen and Kuo, 2011) reported activation energy values of 124 kJ/mol for cellulose but in the temperature range of 200°C to 300°C under isothermal heating condition. Also, cellulose activation energies of 194 kJ/mol and 195 kJ/mol in the temperature range of 300°C to 400°C were reported by Kissinger and Kamal's method (Alvarez and Vázquez, 2004). These different values of activation energies are the result of not only different calculation methods as documented by Gaur and Reed (1998) and Chen and Kuo (2011) but also the different crystallinity of the cellulose being used in these studies.

As shown in Figure 2.4b, the activation energy of xylan was in the range of 88 kJ/mol to 348 kJ/mol in the fractional conversion range of 0.1 to 0.4 with an additional high activation energy 745 kJ/mol shown at the fractional conversion 0.37 corresponding to temperature 225°C. Otherwise for temperatures from 185 to 215 °C, the activation energy values fall between 150 and 250 kJ/mol. Similar, activation energy values have been reported in the literature, for example, 252 kJ/mol in the temperature range of 200°C to 300°C using isothermal heating (Chen and Kuo, 2011), Some other studies reported activation energy values are 109 kJ/mol in the temperature range of 225-265 °C and 105

kJ/mol in the temperature range of 270-320 °C (Ramiah, 1970). Again, varying values of activation energy for xylan are directly related to the source of xylan and the method used in calculating the activation energy.

As shown in Figure 2.4c, the activation energy of lignin constantly increased as a response to rising temperature from 50 to 370°C in the fractional conversion range of 0.01 to 0.5. A major increase in activation energy was calculated in the fractional conversion 0.4 to 0.5 corresponding to the temperature range of 340 to 370°C. The maximum activation energy of lignin was 801 kJ/mol at a fractional conversion of 0.5. Lignin activation energy was reported to be 38 kJ/mol (Chen and Kuo, 2011) under isothermal heating condition, and 284 kJ/mol (Murugan et al., 2008) in the temperature range of 200°C to 300°C. Different activation energy values of lignin may be attributed to the calculation methods, source of lignin, and the method used in the extraction of lignin. For example, Ramiah (Ramiah, 1970) reported that lignin extracted from spruce wood sawdust by periodate oxidation and hydrolysis had an activation energy value of 54.39 kJ/mol whereas lignin extracted from douglas fir by digesting in sulfuric acid and hydrolysis had an activation energy value of 79.50 kJ/mol. Also, lignin type changes with wood species. Softwood and hardwood have varying proportions of three monomers (p-coumaryl alcohol; coniferyl alcohol; and sinapyl alcohol), which are precursors to lignin polymers. Hardwood lignin contains mainly coniferyl and sinapyl-based alcohols whereas softwood lignin contains mainly coniferyl alcohol with little p-coumaryl alcohol.

2.3.3. Thermo-Chemical Decomposition Behavior of Wood Components

Thermogravimetric Analysis

Experimental char yields were 14.74% for sapwood, 14.26% for heartwood, and 22.69 for bark samples of yellow-poplar. An attempt was made to calculate the char yields for sapwood, heartwood, and bark using their chemical composition data presented in Table 2.5. TGA char-yield data for individual model wood polymers (cellulose, xylan, and lignin) are presented in section 3.2, and assumed 26.9% char yield from extractives (Raveendran et al., 1996). The calculated and measured char yields (calculated, measured) were (10.55%, 15.61%) for sapwood, (11.22%, 15.60%) for heartwood, and (17.02%, 23.45%) for red oak samples. As can be seen, the char yields calculated from models of wood polymers and the chemical composition of wood are different from the experimentally measured char yields. These differences are directly related to the differences in the chemical nature of cellulose,

xylan, and lignin used as model wood polymers and those actually present in the sapwood, heartwood, and bark samples.

Figure 2.5. Thermo-gravimetric analysis results showing rate of percentage weight remaining when samples of (a) yellow-poplar and (c) red oak's components (bark, sapwood and heartwood), and rate of fractional changes when samples (b) yellow-poplar and (d) red oak's components (bark, sapwood and heartwood) heated from 50°C to 700°C at the heating rate of 10°C/min under an inert atmosphere.

Raveendran et al., (1996) reported that crystallinity of cellulose varies from 34.4 for Whatman cellulose to 91.5 for highly crystalline cellulose used in chromatography instrument columns and it directly affects thermal decomposition of wood. Wood cellulose crystallinity is somewhere around 68.9. Due to the difference in crystallinity, wood cellulose produced 14% char whereas Whatman cellulose produced 2.5% char. Therefore, low crystallinity cellulose produces low quantities of char because it has more amorphous regions to react during pyrolysis than highly crystalline cellulose. Raveendran et al. did not find such large differences between xylan and wood extracted hemicellulose char yields. Char yields for lignin polymers may vary from 47.1 for acid-extracted lignin to 40.6 alkali-

extracted lignin (Raveendran et al., 1996). There are other methods for lignin extraction as discussed in Fengel and Wegeber (Dietrich Fengel, 2003) and each extraction method significantly alters the amorphous chemical structure of lignin, which might explain different char yields from different lignins obtained from TGA graphics.

The TGA graphics were used to calculate DTG graphics to plot rate of fractional conversion as the function of temperature. The DTG graphics provide visual information as to when pyrolysis reactions are taking place and the rates of fractional conversion. Within the DTG graphics, there are three things to watch for, first, location of peaks, second, relative height of peaks, and third, broadness of DTG graphic on the temperature scale. In the DTG graphic (Figure 2.5), two obvious peaks were observed for bark, sapwood and heartwood in the temperature ranges of 250°C to 350°C and 350°C to 400°C, respectively (Figure 2.5b, Figure 2.5d). The first peak at 280°C accounted for the degradation of hemicellulose and the later peak at 360°C was mainly due to cellulose decomposition. Raveendran et al. reported the following prominent events that can be observed in DTG: mainly moisture evolution below 100°C; start of extractive decomposition between 100 and 250°C, mainly hemicelluloses decomposition between 250 and 350 °C, cellulose decomposition between 350 and 500°C and lignin decomposition beyond 500°C. Interestingly, cellulose and hemicelluloses peaks are more separated for bark samples, whereas, the hemicelluloses peak is visible only as a shoulder for the sapwood and heartwood samples. These separations may very well be explained by noting the cellulose-to-hemicellulose ratios calculated from chemical composition data presented in Table 2.5. The calculated cellulose-to-hemicellulose ratios were 1.9 for sapwood and heartwood and 1.5 for bark of the red oak samples. Similarly, the ratios were 2.1 for sapwood and

heartwood and 1.9 for bark samples of the yellow-poplar. It is evident that a low cellulose-to-hemicellulose ratio produces a clear separation of the hemicellulose peak which is why the red oak bark showed more visible separation of the hemicellulose peak than yellow-poplar bark.

Another visible difference was the height of peaks which correspond to the rate of decomposition. At both peaks, sapwood and heartwood showed higher decomposition rates than bark for both yellow-poplar and red oak. This behavior is caused by the amount of cellulose or hemicellulose present in biomass. For example, sapwood had the highest cellulose content; therefore, it showed the largest peak height at 360°C. In contrast, bark had the lowest cellulose content; therefore, it showed the lowest peak height at the same temperature. Finally, broadness of the DTG curve is associated with lignin and extractive decomposition because both lignin and extractives decompose in a very broad temperature range. The only difference between the two is that extractives decompose at higher rates than lignin but at lower temperatures (Raveendran et al., 1996). Raveendran et al. reported that the extractives derived from wood decomposed between 150 to 400°C, whereas lignin decomposed between 250 and 450 °C. Therefore, a high lignin-to-extractive ratio should provide insight into the broadness of DTG curve. If the DTG curve is broadened towards the right side of the cellulose peak, the lignin-to-extractive ratio is low and vice versa. From the chemical composition data in the Table 2.5, this ratio was 0.6 for yellow-poplar bark and 0.7 for red oak bark. Therefore, extra broadness is visible on the right side of the cellulose peak for red oak bark in the DTG graphics.

Figure 2.6 shows the activation energy and dX/dt curves of (a) bark, (b) heartwood and (c) sapwood for yellow-poplar as a function of fractional conversion from 0.01 to 0.9. These activation energy values should be the result of the combined effects of the individual wood polymers. The key observations about the activation energy pattern for bark, heartwood and sapwood in Figure 2.6 are following: 1. A “three-zone” degradation occurred for sapwood and heartwood (<0.2 fractional conversion; 0.2-0.9 fractional conversion; and >0.9 fractional conversion), 2. A “three-zone” degradation occurred for bark (<0.4 fractional conversion, 0.4 to 0.8 fractional conversion, and >0.8 fractional conversion), and 3. Activation energy values for bark remained higher than the other two wood components for all conversions.

The three-zone degradation for sapwood and heartwood (<0.2 fractional conversion; 0.2-0.9 fractional conversion; and >0.9 fractional conversion) may be explained by their respective zone-temperatures and the chemical compositions of sapwood and heartwood (moisture, extractive, cellulose, hemicellulose, and lignin contents). The activation energy below 0.2 fractional conversions ranged from 265 to 296 kJ/mol, which may very well be related to moisture evolution and extractive decompositions. Both sapwood and heartwood had a total of 14.3% of moisture and extractive content. Also, up to 0.2 fractional conversion, degradation took place below 295 °C, which is the temperature range for moisture evolution and extractive decomposition (Raveendran et al., 1996). The activation energy for moisture evolution below 100 °C is reported to be in the range of 29.35 to 33.78 kJ/mol, which is basically related to the evaporation of the free and some bound water (Mirzaee et al., 2009). Above 100 °C but below 295 °C, all bound water

including water of constitution (water molecules connected to cellulose polymers by high-energy hydrogen bonds) is driven off. In the same temperature range, extractives decompose. In the second zone, mainly cellulose and hemicelluloses decompose between 0.2 and 0.9 fractional conversion temperatures between 295 °C to 365°C. Both sapwood and heartwood had approximately a total of 76% cellulose and hemicellulose and cumulatively 90% of sapwood and heartwood was made-up of moisture, extractives, cellulose, and hemicellulose. The activation energy between 0.2 and 0.9 fractional conversions stayed around 240 to 260 kJ/mol. The reported activation energy values for 0.70 conversion are 209 kJ/mol (Slopiecka et al., 2012) and 265 kJ/mol (Singh et al., 2012). Finally, activation energy above fractional conversion of 0.9 fluctuated between 286 to 449 kJ/mol, mainly for the decomposition of the remaining 10% lignin. Beall reported activation energy of wood lignin decomposition to be 135.98 kJ/mol in the temperature range of 398 °C to 439°C, which was calculated by a differential-difference method (Beall, 1969).

As mentioned before, decomposition of bark also took place in three fractional conversion zones (<0.4 fractional conversion, 0.4 to 0.8 fractional conversion, and >0.8 fractional conversion) but activation energy values for bark remained higher than the other two wood components for all conversions. The first decomposition zone for bark lasted until 0.4 fractional conversion below 315°C, which reflected decomposition of its combined 37% moisture and extractives. The activation energy in this decomposition zone was between 260 and 296 kJ/mol. In the second fractional conversion zone (0.4 to 0.8), the combined 44% hemicellulose and cellulose degraded with activation energy in the range of 256 to 309 kJ/mol until the temperature reached 375°C. After the fractional conversion of 0.8 for bark, the activation energy reached as high as 943 kJ/mol due to lignin decomposition as

temperatures soared above 600 °C. Additionally, overall activation energy values for bark decomposition were attributed to the high extractive and lignin content of the bark compared to the sapwood and heartwood.

Figure 2.6. Activation energy and dX/dt (experimental and calculated) curve of (a) bark, (b) heartwood and (c) sapwood of yellow-poplar as a function of fractional conversion from 0.01 to 1.0.

Figure 2.6 also shows plots for dX/dt calculated using activation energy values, pre-exponential factor values, and an assumed order of reaction equal to 1. The calculated dX/dt curve closely followed the experimental dX/dt curve, which suggested that the isoconversion method applied in this paper for the determination of the kinetics is valid for wood pyrolysis

2.4. Conclusions

Biomass components (bark, sapwood and heartwood) of red oak and yellow-poplar and wood polymers (cellulose, xylan and lignin) were evaluated for calorific value, cell wall specific gravity, proximate analysis, mineral analysis and ultimate analysis. There is no significant difference for the results of the cell wall specific gravity, calorific value and ultimate analysis among bark, sapwood and heartwood for red oak and yellow-poplar. In addition, the thermo-chemical decomposition behavior of the individual wood polymers (cellulose, xylan and lignin) and red oak and yellow-poplar components (bark, sapwood and heartwood) was also examined. Cellulose showed activation energy values in the range of 208 to 381 kJ/mol during decomposition whereas xylan and lignin had maximum activation energy values of 348 kJ/mol and 801 kJ/mol at fractional conversions of 0.4 and 0.5, respectively. The activation energy requirement for wood components remained within the range of 233 kJ/mol to 388 kJ/mol until 365°C and then peaked to roughly 943 kJ/mol, 449 kJ/mol and 298 kJ/mol for bark, heartwood and sapwood at 375°C where major energy input for lignin decomposition is needed. Also, it was observed that the isoconversion methods may not work for all the fractional conversion values for individual wood polymers but the method worked well for the wood components.

CHAPTER 3: CATALYTIC UPGRADING OF PYROLYSIS VAPORS USING BIO-CHARS AS CATALYST

3.1. Introduction

Renewable energy has received renewed attention in recent years in light of the increasing fossil fuel costs, limited fuel sources and environmental concerns. Comparing to other clean energy resources, biomass is an exclusively sustainable renewable resource capable of producing petroleum-like products due to its hydrocarbon content (Dickerson and Soria, 2013). Current biomass conversion technologies for hydrocarbon production are biological, biochemical and thermochemical processes (Demirbas, 2009).

Pyrolysis is one of the most promising thermochemical technologies as it can potentially transform cheap, local, and abundant lignocellulosic biomass into useful solid, liquid and gas products, when processed at temperatures between 400°C and 650°C in the absence of oxygen (Mohan et al., 2006). The pyrolysis technology is further classified into slow pyrolysis and fast pyrolysis categories, depending on heating rates and residence time with relatively slow heating rates ranged from 0.1- 1°C/s and unrestricted residence time from minutes to hours, traditional pyrolysis is considered as slow pyrolysis. In addition, a fast pyrolysis, a relatively new technology, occurs when the biomass is heated at a rate of 10 to 1000°C/s with short residence time (Balat et al., 2009). Fast pyrolysis claims to produce high bio-oil yields and is considered more advantageous than slow pyrolysis (Balat et al., 2009). Chemically, during the pyrolysis process, the biomass decomposes into condensable volatile species, gasses and solid residue, also called bio-char. The volatile species are condensed in the form of a dark viscous liquid also known as bio-oil (Yaman, 2004).

The bio-oil produced by biomass pyrolysis can be used as an alternative energy resource and it may be directly burned for various applications (Bridgwater and Peacocke, 2000). However, the polyphenol polymerization reactions take place in bio-oil during storage (Oasmaa, 2000). These processes gradually change the properties of bio-oil. The polymerizing reactions are intensified when the bio-oil is exposed to light, oxygen and temperatures above 80°C. As a result, the viscosity of bio-oil can change from 10 to 10,000 cp (Oasmaa, 2000). Also, bio-oil has lower pH and higher solid and moisture contents than crude oil leading to storage, corrosion and combustion issues (Oasmaa, 2000).

Catalytic upgrading the volatiles is currently considered as the most promising method to minimize the negative characteristics of bio-oil (Bridgwater, 1996). During the catalytic process, the moisture and oxygen contents of bio-oil are minimized, molecular weight is reduced, and some bio-oil mass is reduced in favor of char and gaseous species (Sekiguchi and Shafizadeh, 1984). The ideal catalyst should be highly active, selective to particular products, resistant to deactivation, readily recycled and cheap. Different catalysts have different reaction mechanisms. Currently, researchers are focusing on two main routes for upgrading; hydrodeoxygenation (HDO) and zeolite cracking. However, both of them have drawbacks. HDO requires large quantities of H_2 at relatively high pressure while zeolite cracking produces relatively low bio-oil yields (Dickerson and Soria, 2013). Chen et al. (2008) pyrolyzed pine wood at 350°C with several additives including respectively: NaOH, Na_2CO_3 , Na_2SiO_3 , NaCl, TiO_2 , HZSM-5, H_3PO_4 and $Fe_2(SO_4)_3$. During the pyrolysis, the main pyrolysis process were expressed as follows:

Basic pyrolysis gasification reaction (Arauzo et al., 1994):

Further secondary gasification reactions:

According to Chen et al. (2008), the alkaline sodium additives (NaOH, Na₂CO₃, Na₂SiO₃) have the most marked effect by decreasing the CH₄ and CO₂ formations and increasing the hydrogen formation. The mineral concentration of red oak bio-char is dominated by potassium, magnesium and calcium. These alkaline minerals have chemical characteristics similar to alkaline sodium.

Although bio-char has not been used as a catalyst in pyrolysis process, it has been successfully used in phenol and toluene cracking, biodiesel esterification catalyzing and methane reforming (Abbas and Wan Daud, 2009; Dehkhoda et al., 2010; Domínguez et al., 2007; Mani et al., 2013). Mani et al. (2013) used slow pyrolysis pine bark bio-char pyrolyzed at 900°C as a low-cost catalyst to decompose toluene. In this study, the catalytic conversion of toluene was studied in a continuous flow packed bed reactor system in the temperature range of 550 – 900 °C under atmospheric pressure. Streams of toluene and water vapors were added to the carrier gas (nitrogen) by two syringe pumps. The mixtures of nitrogen, toluene and water were then transported through a static mixer to the reactor, enclosed in a furnace, containing a 0.45 m preheating zone, followed by 0.03 m of catalyst

(3.8 g catalyst or bio-char). A fractional conversion of 94% toluene was achieved on bio-char catalysts (Mani et al., 2013). In another study, Dehkhoda et al. (2010) mixed 20 g of hardwood bio-char with 200 ml concentrated sulfuric acid (98%, Sigma) to prepare a sulfonated bio-char catalyst. The catalyst was very active in the esterification of free fatty acids and alcohols. To study the possibility of directly converting biogas to syngas, Domínguez et al. (2007) used pyrolyzed coffee hulls bio-char pellets as a potassium-rich catalyst during gasification of a mixture of CH₄ and CO₂ (1:1 ratio). The study indicated that the gasification of CH₄ to H₂ increased and high conversion of CH₄ was also achieved. In addition, bio-char may potentially lead to hydrogen formation during pyrolysis as it contains catalytic inorganic minerals (Aho et al., 2008; Chen et al., 2008; Dehkhoda and Ellis, 2013).

This paper studies the upgrading of pyrolysis vapors using bio-chars (red oak bark bio-char and switchgrass bio-char) its effects on yields and properties woodchip pyrolysis products. The objective of this research was to compare the influence of bio-char catalysis on *ex-situ* pyrolysis vapor upgrading during woodchip pyrolysis. Also the effects of catalyst loading were studied by changing the catalyst-to-biomass ratio 0.1 and 0.4 (by wt.). The term “bio-char” has been used for catalysts (switchgrass and red oak bark bio-chars) and the term “char” describes the residual solid product of woodchip pyrolysis.

3.2. Method and Measurements

3.2.1 Description of pyrolysis reactor

Pyrolysis experiments were performed in a fixed bed reactor with a nine-inch diameter and ten-inch height (Figure 3.1). The reactor was sealed airtight with the biomass

sample inside and then placed in a furnace (Model: BF51728C, Thermo Scientific, NC). To remove air from the sealed reactor, nitrogen gas was constantly purged at the rate of 2 L/min during pyrolysis process. The furnace was heated from room temperature to 500 °C under a continuous nitrogen flow of 2 L/min. The nitrogen gas maintained the pyrolysis reaction under inert conditions. The nitrogen gas also swept the generated vapors into ice bath condensers. The ice bath consisted of five stainless-steel condensers (12” long and 4” diameter). The inner temperature of the reactor during pyrolysis process was continuously recorded by a K-type thermocouple placed at the center of the reactor inside a thermal well. The temperature data were automatically recorded by a data logger (Model: OM-DAQPRO-5300, Omega engineering, Stamford, CT) connected to a computer.

Figure 3.1. Experimental set-up used in pyrolysis includes pyrolysis reactor holding biomass, nitrogen flow, location of thermocouple, and set of condensers.

3.2.2 Pyrolysis Experiments

Fresh samples of mixed wood chips were collected from a nearby sawmill. Samples of switchgrass were collected from a field where it was being grown for research purposes. Red oak bark was collected from a log of red oak harvested from the West Virginia University (WVU) Research Forest. All the samples were oven dried for 24 hours at 103 °C before pyrolysis. Prior to the pyrolysis experiments, the weights of the empty reactor and condensers were recorded. After that, about pre-weighted 1000 g (or half volume of the reactor) of biomass was placed inside the reactor. During heating of the sealed reactor, pyrolysis of the biomass occurred and volatiles were formed. The volatiles were condensed in the ice bath. The remaining uncondensed gases were filtered and released to the atmosphere. Before releasing the gases to the atmosphere, gas samples were collected when reactor temperature was 300, 400, and 500 °C. The gas samples were collected using airtight GC syringes (Model: 1000 series, Hamilton, NV). After pyrolysis, the weights of the reactor with char inside and the condensers with bio-oil inside were recorded. The weight of char and bio-oil were calculated using the reactor and condenser weights recorded before and after reaction. This allowed the pyrolysis product yields to be calculated. The gas yield was calculated by difference.

To study catalytic upgrading of pyrolysis vapors, about 300-350 g of bio-char (switchgrass bio-char or red oak bark bio-char) were evenly placed on top of the woodchips. To produce catalyst bio-char from switchgrass and red oak bark, both of these biomasses were individually pyrolyzed at 500°C temperature.

3.2.3 Experimental design

Completely Randomized Design was used to evaluate effects of three treatments. The three treatments were the use of no bio-char (control), switchgrass bio-char, and red oak bark bio-char for the catalytic refining of pyrolysis vapors. To do this, a layer of pre-weighted catalyst bio-char (switchgrass char or bark char) was evenly placed on top of the woodchips inside the reactor. This allowed the pyrolysis vapors to pass through the bio-char catalyst before condensation. The woodchips were pyrolyzed without bio-char catalysts as a control experiment. Each experiment was replicated twice, therefore a total of six experiments were performed. The char and bio-oil yield and data on the bio-oil properties were statistically analyzed to test the hypothesis that catalytic modification of pyrolysis vapors using bio-char catalysts reduces bio-oil yields.

3.2.4 Analytical measurements

The composition of gas samples were determined by a gas chromatograph (Model: Clarus GC 580, Perk Elmer Waltham, MA). In addition, the calorific value of woodchip char was measured using a bomb calorimeter (Model: 6300 Calorimeter, Parr Instrument Company, Moline, IL) according to the ASTM D5865 standard (Materials, 1998) without accounting for heat of reactions for nitric and sulfuric acids. It is important to mention that some bio-oil samples failed to ignite inside the bomb calorimeter. In such case the calorific value was determined using an empirical equation (Channiwala and Parikh, 2002). Ultimate analysis of char and bio-oil was performed using a CHNS analyzer (Model: Series II CNHS/O Analyzer 2400, PerkinElmer, Waltham, MA). Proximate analysis (moisture, volatile matter, fixed carbon and ash) was carried out using a proximate analyzer (Model: LECO 701, LECO Corporation, St. Joseph, MI, USA) following the ASTM

D3174 standard (ASTM, 2011). The specific gravity and moisture content of bio-oil was measured according to ASME PTC 19.16 Standard and ASTM D4928 Standard, respectively. The moisture content was measured by a compact Karl Fisher titrator (Model: V30, Mettler Toledo, OH). The pH value was measured by means of an accumet pH meter (Model: AB15, Fisher Scientific, USA). The bio-char catalysts were tested for mineral composition and chemical composition at the Agricultural and Environmental Sciences Laboratory, University of Georgia.

3.2.5 Efficiency of char and bio-oil production

The energy conversion efficiency (η_{Energy}) and carbon yield (C_{Yield}) of wood chips char and bio-oil were estimated via the following expressions:

$$\eta_{Energy} = Y_{Char/bio-oil} \frac{HHV_{Char/bio-oil}}{HHV_{Feedstock}} \quad (3 - 6)$$

Where η_{Energy} = energy conversion efficiency; $Y_{Char/bio-oil}$ = yield of bio-char or bio-oil (%); $HHV_{Char/bio-oil}$ = calorific value of bio-char or bio-oil (MJ/kg); and $HHV_{Feedstock}$ = calorific value of the feedstock biomass.

$$C_{Yield} = Y_{Char/bio-oil} \frac{C_{Char/bio-oil}}{C_{Feedstock}} \quad (3 - 7)$$

Where C_{Yield} = carbon yield; and C = carbon content of the feedstock, i.e.-char or bio-oil (%) (Das, 2011).

3. 3. Results and Discussion

3.3.1. Feedstock Biomass and Bio-char Catalyst Characterization

Table 3.1 shows the ultimate analysis (carbon, hydrogen, nitrogen and sulfur contents), proximate analysis (moisture, ash, volatile and fixed carbon contents), and selected mineral contents of wood chip feedstock, and bio-char catalysts made from switchgrass and red oak bark. The 74.44% carbon content in red oak bark bio-char catalyst was significantly lower than the carbon content of 77.52% present in switchgrass bio-char catalyst (p-value=0.03). Similar carbon content (78.3%) for switchgrass bio-char has been reported (Imam and Capareda, 2012). High carbon content in catalysts is expected to provide a more reactive carbon surface for refining of pyrolysis vapor refining. However, the fixed carbon content (ash-free basis) of red oak bark bio-char catalyst (77.78%) was significantly higher than that of the switchgrass bio-char catalyst (71.64%). The difference between carbon content and fixed carbon content may be considered as reactive carbon which may actively take part in binding with oxygen present in the chemical compounds of pyrolysis vapors. This difference is more significant for switchgrass bio-char than for red oak bark bio-char, which again showed that the switchgrass bio-char catalyst has more reactive carbon than red oak bark bio-char catalyst. At the same time, high ash-free carbon (fixed carbon) should provide a reducing matrix for vapor refining. Additionally, the ash content in switchgrass bio-char catalysts was 6.87%, which was significantly higher than the ash content in red oak bark bio-char catalysts (1.25%). High ash content represents high inorganic matter in bio-chars which should exhibit catalytic effects during the pyrolysis process.

Mineral composition of switchgrass and red oak bark bio-chars are also presented in Table 3.1. Si and Al contents are of most important for catalytic purposes. Previous study found that simple ZSM-5 catalysts have a microporous crystalline structure containing oxides of Si and Al (Derouane et al, 1981). Also, the negatively charged Al_3O_4^- , which provides acid reactive sites for cracking are created when Al_3^+ substitutes for Si_4^+ at appropriate places in the catalyst structure (Crook et al., 1993). In this case, the presences of Al and Si in ash, especially Si to Al ratio would be a vital factor to determine the reaction selectivity of catalysts. The Si to Al ratio for FCC (Fluidized Cracking Catalyst) catalyst is 1.84 (Gerber et al., 1999), and for ZSM-5 catalyst is 65.47 (Dao et al., 1987). In this study, the Si to Al ratio for switchgrass bio-char was 0.2, and for red oak bark bio-char was 0.02.

Table 3.1. Ultimate analysis (carbon, hydrogen, nitrogen and sulfur content (% d.b.)), proximate analysis (moisture, ash, volatile and fixed carbon (% d.b.)) of clean woodchip, switchgrass bio-char and red oak bark bio-char. Mineral composition in parts per million (ppm) of switchgrass bio-char and red oak bark bio-char.

	Woodchip Raw	Switchgrass Bio-char	Red oak bark Bio-char
Carbon (%)	44.34 ± 0.11	77.52 ± 0.78	74.44 ± 0.32
Hydrogen (%)	5.81 ± 0.11	2.65 ± 0.03	2.69 ± 0.03
Nitrogen (%)	0.2 ± 0.02	1 ± 0.12	0.94 ± 0.12

3.3.2 Effect of Type of Bio-Char Catalysts

Bio-oil and Char Yields

Table 3.2 shows the yields of char and bio-oil produced from woodchip pyrolysis. The gas yields were calculated by difference. The pyrolysis vapors were upgraded using bio-chars as catalysts prior to condensation. The catalyst loadings were kept 40% by weight. Two types of bio-char catalysts were tested: switchgrass bio-char and red oak bark bio-char. The woodchip without catalyst produced approximately 29% char and 49% bio-oil. In the literature, char and bio-oil yields for hardwood has been reported as: 15.90% char and 65.00% bio-oil were produced from beech wood in fluid-bed fast pyrolysis at 500°C (Greenhalf et al., 2013) and 23.01% char and 60.34% bio-oil were produced from commercial lignocellulose biomass (Lignocel HBS 150–500) originating from beech wood in fixed bed reactor through flash pyrolysis at 500°C (Stephanidis et al., 2011). In addition, Kim et al. reported that xylem tissues of oak produced 65.7% bio-oil and 14.1% bio-char, and xylem tissues of eucalyptus produced 59.2% bio-oil and 14.9% bio-char at 500°C in fluid-bed through fast pyrolysis (Kim et al., 2013). One possible reason of the relatively low bio-oil yield and high char yield observed in the present study could be due to the different moisture content of feedstock and type of pyrolysis used. Both studies referred above had used room temperature air drying method for feedstock drying. The moisture contents of the pyrolyzed biomass feedstock were 8% (Greenhalf et al., 2013) and 5% (Stephanidis et al., 2011). In contrast, the present study used oven-dried (bone-dried) biomass at temperature 103 °C. In another study, Galina Dobeles (2007) reported that the water content in bio-oil decreased to 19-20 % from 25-28 % in bio-oil after drying the wood sample with moisture

content 8.5-9% at 200°C for 30 minutes (Galina Dobeles, 2007). Another reason could be the particle size of feedstock, the woodchip size, not the average particle size, in this study was ranged from $\frac{1}{2}'' \times \frac{1}{2}'' \times \frac{1}{10}''$ to $2'' \times 2'' \times \frac{1}{5}''$, in addition, the particle size of Kim et al was 0.5 mm, which was much smaller than the woodchip size used in this study. Gaston et al. reported that larger particles led to more tar and char formation because less volatile were produced during the pyrolysis process (Gaston et al., 2011). There is another possibility getting small char yields when using very small particles for pyrolysis. During pyrolysis of very small particles, the char might be pneumatically carried from the reactor into the bio-oil condensers and contribute to the overall weight of the bio-oil.

In addition, heating rate also greatly affects bio-oil yield. Onay reported that high heating rate will result in high bio-oil yield. The yield of bio-oil was 7 wt.% higher at heating rate 300 °C /min than at heating rate 100 °C /min (Onay, 2007). The average heating rate achieved in the present study was around 9 °C/min which was significantly lower than the 500-1000 °C/s in previous study.

Table 3.2. Percent char and bio-oil yields (mean $\pm$ SD, replications=2) produced from pyrolysis of clean woodchip at 500°C followed by catalytic upgrading of pyrolysis vapors using bio-char catalysts made from switchgrass and red oak wood bark. The catalyst to woodchip ratio (by weight) was kept approximately 0.40.

	Loading	Char	Bio-oil	Gas
No catalyst	0	29.09 $\pm$ 0.22	49.31 $\pm$ 0.08	21.61 $\pm$ 0.31
Switchgrass catalyst	0.4	28.56 $\pm$ 1.60	46.81 $\pm$ 0.67	24.63 $\pm$ 0.93
Red oak bark catalyst	0.4	29.82 $\pm$ 0.56	48.68 $\pm$ 1.12	21.51 $\pm$ 0.56

Analysis of variance, for catalyst to woodchip loading of 0.4, showed that the type of catalysts had significant effect on bio-oil yields (p-value= 0.041). Between the two catalytic bio-chars, the switchgrass bio-char had a more profound effect on bio-oil yields

than red oak bark bio-char (p-value= 0.033). In fact, the switchgrass bio-char catalyst reduced bio-oil yields from 49.31% (no catalysis) to 46.81 % (p-value= 0.022). The different catalytic performances of the two bio-char catalysts could be caused by the differences of Si to Al ratios. The Si to Al ratio in switchgrass bio-char was ten times higher than that in red oak bark bio-char. In this case, more Al_3^+ substitutes for Si_4^+ at the surface of the switchgrass bio-char and consequently creates more reactive sites for vapor cracking.

As expected, the *ex-situ* catalytic vapor upgrading of pyrolysis volatiles did not affect residual char yields from woodchip pyrolysis. The yields of residual chars were 28.56% and 29.82% when woodchips were pyrolyzed with switchgrass bio-char and red oak bark bio-char, respectively. In contrast, Stephanidis et al. reported that the total char yields were affected during *ex-situ* catalytic upgrading of pyrolysis vapors. According to Stephanidis et al., commercial lignocellulose biomass (Lignocel HBS 150-500) originating from beech wood produced, approximately, 25.72% char (out of which 2.71% was coke deposited on silicatlite catalyst), 25.88% char (out of which 2.87% was coke deposited on H-ZSM-5 catalyst) and 30.66% char (out of which 7.65% was coke deposited on Al-MCM-41 catalyst) (Stephanidis et al., 2011), while the non-catalyst char yield was 23.01%. The main cause for the contrasting results was that Stephanidi et al. also accounted for the secondary char formation in the catalysis reactor. During *in-situ* catalysis, Compton et al. reported increases in char yields for oak pellets from 26.0% (no catalysis) to 37.1% - 48% when different types of catalysts were mixed with the oak pellet biomass.

It is expected that *ex-situ* catalysts would alter bio-oil yields and its properties. The yields of bio-oil were 46.26% and 49.86% due to *ex-situ* catalysis with switchgrass bio-char and red oak bark bio-char, respectively. Stephanidis et al. reported commercial

lignocellulose biomass (Lignocel HBS 150-500) originating from beech wood produced 47.58%, 43.95% and 45.34% bio-oil yields through vapor upgrading of pyrolysis gases by using catalyst silicalite, H-ZSM-5 and AI-MCM-41, respectively (Stephanidis et al., 2011). Among these three catalyst, H-ZSM-5 showed the most effectiveness, which was observed in another study as well (Huber, 2006). The measured catalytic activity was attributed to the strong Brönsted-type zeolitic acidity of H-ZSM-5. Oil yields of oak pellets ranged from 39.9% to 58.9% were produced in a packed bed at 500°C when the oak pellets were mixed with various catalyst pellets as biomass-to-catalyst ratio of 1:5 (Compton et al., 2011). Both Compton et al.'s and Stephanidis et al.'s studies used mesoporous aluminosilicates as the catalyst, however the yield results varied between *in-situ* and *ex-situ* catalysts. The change in char yield in *in-situ* catalytic pyrolysis (17.99%) was higher than in *ex-situ* pyrolysis (7.66%), while the change in liquid yield in *in-situ* catalytic pyrolysis (9.6%) was lower than in the *ex-situ* process (14.89%).

Effect of Catalyst Loading on Char and Bio-oil Yields

Table 3.3 presents pyrolysis product yields for two catalyst loading ratios of 0.1 and 0.4 for switchgrass bio-char catalyst during woodchips pyrolysis. As shown in Table 3.3, there is no significant difference between yields of char due to catalyst loading of 0.4 compared to that with no catalyst condition (p-value=0.23). Adding switchgrass catalyst at a loading ratio of 0.4 reduced bio-oil yield from 49.31% (no catalyst) to 44.81. Changing catalyst loading from 0.1 to 0.4 reduced bio-oil yields from 46.81% to 44.81%. The decrease in bio-oil yield may very well be explained by increased gas yields (Table 3.3). Thangalazhy-Gopakumar et al., (2012) varied catalyst (H^+ ZSM-5) from zero to nine times the biomass weight during pyrolysis of algae at 500 °C. They found that increasing catalyst

loading decreased the overall bio-oil yields. However, yields of aromatic hydrocarbons increased from 0.9 to 25.8% due to the presence of more active sites on the catalyst (Thangalazhy-Gopakumar et al., 2012).

Table 3.3. Percent char and bio-oil yields (mean $\pm$ SD, replication=2) produced from pyrolysis of clean woodchip at 500°C followed by catalytic upgrading of pyrolysis vapors using bio-char catalysts made from switchgrass with different catalyst to woodchip ratio (by weight) as 0.1 and 0.4.

	Loading	Char	Bio-oil	gas
No catalyst	0	29.09 $\pm$ 0.22	49.31 $\pm$ 0.08	21.61 $\pm$ 0.31
Switchgrass bio-char catalyst	0.1	28.56 $\pm$ 1.6	46.81 $\pm$ 0.67	24.63 $\pm$ 0.93
Switchgrass bio-char catalyst	0.4	26.74 $\pm$ 1.05	44.81 $\pm$ 1.4	28.45 $\pm$ 0.35

Changes in Pyrolysis Gas Composition

Table 3.4 shows gas composition of pyrolysis gasses generated at 300, 400, and 500 °C at a catalyst-to-biomass ratio of 0.4. *Ex-situ* bio-char catalysis affected gas composition at all three temperatures (300, 400, and 500°C) for which gases were sampled. At 300°C, both bio-chars catalytically produced more CO and CO₂ than the control condition (p-value<0.001). When comparing two bio-chars, the red oak bark bio-char produced more carbon dioxide and monoxide (p-value= 0.0014). However, at temperature 400°C, there is no significant difference of methane and CO release due to the addition of the either bio-chars but more hydrogen was released due to the use of switchgrass bio-char catalyst (3.74%) than red oak bark bio-char catalyst (0.48%) (p-value=0.0129) and control (0.82%) (p-value=0.0186). The CO₂: CO ratio was in the range of 1.5:1 to 2:1 at all three temperatures. Previous study by Compton et al. (2011) has reported CO₂:CO of 1:1 when the oak pellets were mixed with various catalyst in a biomass-to-catalyst ratio of 1:5 in a packed bed at 500°C (Compton et al., 2011). Also, in Compton et al.'s study, the amounts of

CO and CO₂ were significantly higher than that of the control. However, in Stephanidis et al.'s study, the yield of CO₂ was significantly decreased from 55.17% to 42.57, 38.68 and 45.42%, when commercial lignocellulose biomass (Lignocel HBS 150-500) originating from beech wood was pyrolyzed and vapors were upgraded through silicalite, H-ZSM-5 and AI-MCM-41 catalysts, respectively. The yields of CO and ethylene were significantly increased (Stephanidis et al., 2011). It may be concluded that bio-char catalysts gasify bio-oil compounds into carbon dioxide, carbon monoxide, and hydrogen, thereby, reducing total bio-oil yields.

Table 3.4. Percent of gas compositions (mean $\pm$ SD, replication=2) produced during vapor upgrading pyrolysis of clean woodchip at 300°C, 400°C and 500°C followed by catalytic upgrading of pyrolysis vapors using bio-char catalysts made from red oak bark and switchgrass loaded as catalyst to woodchip ratio (by weight) 0.4.

300°C	O ₂	H ₂	CO ₂	Ethylene	Ethane	Methane	CO
No Catalyst	18.59 $\pm$ 0.03	0.01 $\pm$ 0	0.83 $\pm$ 0.03	0 $\pm$ 0	0 $\pm$ 0	0.19 $\pm$ 0.01	0.06 $\pm$ 0.08
Red oak bark bio-char	4.41 $\pm$ 0.28	0.45 $\pm$ 0.13	28.23 $\pm$ 0.65	0.2 $\pm$ 0.25	0.57 $\pm$ 0.37	6.5 $\pm$ 0.81	20 $\pm$ 2.26
Switchgrass bio-char	4.91 $\pm$ 0.11	0.13 $\pm$ 0.01	24.53 $\pm$ 0.08	0 $\pm$ 0	0 $\pm$ 0	0.69 $\pm$ 0	10.85 $\pm$ 0.04

Red oak bark bio-char	8.12 $\pm$ 0.16	0.62 $\pm$ 0.1	29.35 $\pm$ 0.11	0.67 $\pm$ 0.01	1.96 $\pm$ 0.07	10.69 $\pm$ 0	19.07 $\pm$ 0.08
Switchgrass bio-char	5.85 $\pm$ 0.04	0.74 $\pm$ 0.05	19.6 $\pm$ 0.06	0.33 $\pm$ 0.02	1 $\pm$ 0.06	5.96 $\pm$ 0.05	12.78 $\pm$ 0.01

Char and Bio-oil Properties

Table 3.5 shows the pH and moisture content in bio-oil produced from catalytic pyrolysis of woodchips using two catalysts (red oak bark bio-char and switchgrass bio-char) and without catalyst. The pH values of bio-oil produced from vapor upgrading pyrolysis (pH=2.02 for the red oak bark bio-char catalyst and pH=2.23 for the switchgrass bio-char

catalyst) were significantly higher than non-catalytic pyrolysis (p-value=0.0009). Also, between the two catalysts, switchgrass bio-char showed more effect on the pH value than red oak bark bio-char catalyst (p-value=0.0029). High pH value should, relatively, decrease the corrosive activity of the bio-oil, and lower the material corrosion resistivity requirement for the reactor and containers. Similar results were presented by previous studies (Agblevor et al., 2010; Compton et al., 2011). The pH value increased from 1.63 to as high as 3.08 when the oak pellets were pyrolyzed with various catalyst (Compton et al., 2011). Also, the pH value increased from 2.82 to 3.45 when hybrid poplar wood was pyrolyzed with an ExxonMobil catalyst HZSM-5 at 500 °C (Agblevor et al., 2010).

Table 3.5. pH and percentage moisture content (mean $\pm$ SD, replication=2) in the bio-oil produced from woodchip pyrolysis at 500°C followed by catalytic upgrading of pyrolysis vapors using bio-char catalysts made from switchgrass and red oak wood bark. The catalyst to woodchip ratio (by weight) was kept approximately 0.4.

	Loading	pH	Moisture content (%)
No catalyst	0	1.9 $\pm$ 0.07	44.37 $\pm$ 4.43
Red oak bark bio-char catalyst	0.4	2.02 $\pm$ 0.02	51.97 $\pm$ 6.73
Switchgrass bio-char catalyst	0.4	2.23 $\pm$ 0.05	51.83 $\pm$ 3.02

In addition, moisture content significantly increased from 44.37% to as high as 51.97% after vapor upgrading was performed using the two bio-char catalysts. Previous studies also reported an increase in water fraction in bio-oil. In one report, the non-catalytic bio-oil moisture content in bio-oil was 21.40% for beech wood pyrolysis reactions (Stephanidis et al., 2011). The moisture content increased from 21.40% to 30.80%, 33.97% and 30.06% when beech wood pyrolysis vapors were upgraded using silicalite, H-ZSM-5 and AI-MCM-41 catalysts, respectively. The increased water fraction was attributed to enhanced dehydration reactions (Stephanidis et al., 2011).

The calorific value (HHV) of bio-oil was calculated by the method presented by Channiwala et al. (Channiwala and Parikh, 2002). The method is presented below with an average absolute error of 1.45% and bias error of 0.00%:

$$\text{HHV} = 0.3491\text{C} + 1.1783\text{H} + 0.1005\text{S} - 0.1034\text{O} - 0.0151\text{N} \quad (3)$$

$0\% \leq \text{C} \leq 92.25\%$, $0.43\% \leq \text{H} \leq 25.15\%$, $0.00\% \leq \text{O} \leq 50.00\%$, $0.00\% \leq \text{N} \leq 5.60\%$, $0.00\% \leq \text{S} \leq 94.08\%$, $0.00\% \leq \text{A} \leq 71.4\%$, $4.745 \text{ MJ/kg} \leq \text{HHV} \leq 55.345 \text{ MJ/kg}$ where, C, H, O, N, S and A represents carbon, hydrogen, oxygen, nitrogen, sulfur and ash contents of material, respectively, expressed in mass percentages on a dry basis. When calculating calorific values for bio-oils, hydrogen and oxygen contents present in the form of moisture were discounted using moisture content data from the elemental analysis.

Table 3.6 presents ultimate analysis and calorific value of chars and bio-oils produced from woodchip pyrolysis with and without vapor upgrading. The catalysts used in this study did not significantly change either elemental composition or calorific values of chars and bio-oils (p-value =0.4880). Demirbas (2004)'s pyrolyzed trunkbarks at 500 °C without any catalyst and reported carbon contents and calorific values for resulting char and bio-oil. Demirbas reported 68.8% carbon content and 34.6 MJ/Kg calorific value in bio-oil, also, 87.9% carbon content and 33.2 MJ/Kg calorific value in chars (Demirbas, 2004). The different calorific values of bio-oil may attribute by the different measurement methods. Demirbas used bomb calorimeter to collect the higher heating values. In addition, trunkbark has higher HHV (21.7 MJ/Kg) than the mixed woodchip used in this study.

Table 3.6. Calorific value (HHV) and elemental composition (CHNS) of raw, Chars and bio-oils produced from woodchip with and without using switchgrass and red oak bark bio-chars as pyrolysis vapor upgrading catalysts at catalyst to biomass ratio loading of 0.4 at dry basis.

		Carbon (%)	Hydrogen (%)	Nitrogen (%)	Sulfur (%)	HHV (MJ/Kg)
No catalyst	Raw	44.34 ± 0.11	5.81 ± 0.11	0.2 ± 0.02	0.49 ± 0.09	19.17 ± 0.76
	Char	86.72 ± 0.94	2.8 ± 0.08	0.59 ± 0.16	0 ± 0	33.12 ± 0.18
	Bio-oil	54.95 ± 4.16	2.05 ± 3.25	0.81 ± 0.11	0.72 ± 0.42	19.28 ± 4.53
Red oak bark bio-char catalyst	Char	87.23 ± 0.9	2.71 ± 0.05	1.33 ± 0.15	0 ± 0	33.94 ± 1.22
	Bio-oil	58.63 ± 10.87	0.67 ± 0.87	1.1 ± 0.14	0.88 ± 0.39	22.96 ± 6.92
Switchgrass bio-char catalyst	Char	85.79 ± 2.05	2.94 ± 0.16	2.13 ± 1.52	0.06 ± 0.09	32.44 ± 0.78
	Bio-oil	54.32 ± 7.81	1.94 ± 2.75	0.74 ± 0.46	0.98 ± 0.21	17.65 ± 3.73

Energy and Carbon distribution

Table 3.7 presents feedstock energy and carbon distribution in char and bio-oil (water free basis). Both of the energy yield and carbon yield of bio-oil were not significantly affected by the catalyst (p-value=0.5026; p-value=0.2618). Woodchips pyrolysis captured 50.30% of the feedstock energy and 56.67% of the carbon in the char and 27.58% of the feedstock energy and 31.72% of the feedstock carbon in the bio-oils. Overall, pyrolysis products (char and bio-oil) captured 77.88% feedstock energy and 88.39% feedstock carbon.

Also, the carbon yields in chars (p-value=0.6757) were not significantly affected by the use of catalyst. However, switchgrass bio-char catalysis reduced the energy yield in char from 50.30% to 47.31% (p-value= 0.005) and it had a more pronounced affect than red oak bio-char catalysis (p-value=0.026). The energy yield (50.30%) of char produced from red oak bark bio-char catalysis was significantly higher than the energy yield of char (50.30%) produced from non-catalytic pyrolysis (p-value=0.0236) and switchgrass bio-char catalytic pyrolysis (p-value=0.005).

Table 3.7. Energy and carbon distribution of bio-char and bio-oil yield (dry basis) from clean wood chips, and using switchgrass and red oak bark bio-chars as pyrolysis vapor upgrading catalyst (catalyst to biomass ratio of 0.4) .

		Energy yield (%)	Carbon yield (%)
No catalyst	Cchar	50.30 ± 0.67	56.67 ± 1.11
	Bio-oil	27.58 ± 7.26	31.72 ± 0.78
Switchgrass bio-char catalyst	Cchar	47.31 ± 0.16	55.95 ± 5.65
	Bio-oil	19.06 ± 4.63	25.06 ± 3.08
Red oak bark bio-char catalyst	Char	52.52 ± 0.99	59.02 ± 1.10
	Bio-oil	25.20 ± 7.09	34.06 ± 7.09

Therefore, on average, the pyrolysis process is successful in retaining 78% of the energy and 89% of the carbon from the feedstock in its pyrolysis products. The carbon present in chars is a fixed form of carbon, which does not decompose naturally.

3.4. Conclusion

In this study, effect of bio-char catalysis for *ex-situ* refining of pyrolysis vapors was documented. The pyrolysis product yield showed that using switchgrass bio-char as a catalyst for refining pyrolysis vapors significantly reduced bio-oil yields from 49.37% to 44.81%. Among the two bio-chars tested for pyrolysis vapor refining, the switchgrass bio-char was more effective than red oak bio-char, possibly due to its high Si/Al ratio. The Si/Al ratio of switchgrass bio-char was 0.2 whereas the same ratio for red oak bio-char was 0.024. Analyses of gas samples collected at 300, 400, and 500 °C revealed that the switchgrass bio-char vigorously gasified bio-oil compounds at 300 and 400 °C into carbon monoxide, hydrogen, and carbon dioxide. At 400 °C, hydrogen content increased from 0.82% to 3.74%, carbon dioxide content increased from 21.16% to 32.33%, and carbon monoxide content increased from 16.49% to 23.19% for the switchgrass catalyst compared to pyrolysis with no catalyst. It was also inferred from the results that changing catalyst loading from 0.1 to

0.4 for the switchgrass catalyst also reduced bio-oil yields. Use of switchgrass not only reduced bio-oil yields, it also increased moisture content in the product bio-oils.

The significance of the study is that it provides a basis for developing selected bio-chars further into pyrolysis vapor refining catalysts. The results clearly demonstrate that the bio-chars having high Si/Al ratio exhibit cracking characteristics. Some biomass with such properties are switchgrass and rice husk. The bio-chars produced from these biomass may be further modified for enhanced catalytic properties. These enhancements include: activation of bio-chars, acidification of bio-chars, and deposition of metals on bio-chars.

CHAPTER 4: SUMMARY

In the first phase of this study, the pyrolysis kinetics of different wood polymers (cellulose, hemicellulose and lignin) and wood physical components (bark, sapwood and heartwood) were compared. The isoconversion method was applied to estimate activation energy of wood polymers and wood physical components during decomposition. In the second phase of this study, switchgrass bio-char and red oak bark bio-char were tested as catalysts during vapor upgrading of pyrolysis products. The catalyst performance was evaluated by measuring char and bio-oil yields and the characterization of bio-oil and char produced from vapor upgrading during pyrolysis of woodchips.

Results from the first phase of the study showed no significant difference for the results of the cell-wall specific gravity, calorific value and ultimate analysis among bark, sapwood and heartwood for red oak and yellow-poplar. In addition, cellulose showed activation energy values in the range of 208 to 381 kJ/mol during decomposition whereas xylan and lignin had maximum activation energy values of 348 kJ/mol and 801 kJ/mol at fractional conversions of 0.4 and 0.5, respectively. The activation energy requirement for wood components remained within the range of 233 kJ/mol to 388 kJ/mol until 365°C and then peaked to roughly 943 kJ/mol, 449 kJ/mol and 298 kJ/mol for bark, heartwood and sapwood, respectively at 375°C where major energy input for lignin decomposition was needed. Also, it was observed that the isoconversion methods may not work for all the fractional conversion values for individual wood polymers but the method worked well for the wood components.

The results of the second phase of the study showed that both catalysts at the loading ratio of 0.4 (by weight) had a significant effect on bio-oil yields. The bio-oil yield decreased from 49.31% (no catalyst) to 44.81% (switchgrass bio-char catalyst) and 48.68% (red oak bark bio-char catalyst). Additionally, there was no significant change in char yields.

Use of a catalyst changes some bio-oil properties (moisture content and pH). Moisture content increased from 44.37% to roughly 52.0%. Increase in pH of bio-oil was also recorded due to the presence of catalyst. In addition, the gas composition changed due to presence of catalysts. For example, switchgrass bio-char cracked some bio-oil compounds at 300 and 400 °C into carbon monoxide, hydrogen, and carbon dioxide. At 400 °C, the hydrogen content increased from 0.82% to 3.74%, carbon dioxide content increased from 21.16% to 32.33%, and carbon monoxide content increased from 16.49% to 23.19% for pyrolysis with switchgrass catalyst compared to that with no catalyst. Additionally, use of catalyst decreased the carbon yield in bio-oil when using switchgrass bio-char as catalyst.
