ABSTRACT

We have analysed the long- and short-term time dependence of the pulse arrival times and the pulse detection rates for eight rotating radio transient (RRAT) sources from the Parkes Multibeam Pulsar Survey. We find significant periodicities in the individual pulse arrival times from six RRATs. These periodicities range from ~30 min to 2100 d, and from one to 16 independent (i.e. non-harmonically related) periodicities are detected for each RRAT. In addition, we find that pulse emission is a random (i.e. Poisson) process on short (hour-long) time-scales but that most of the objects exhibit longer term (months to years) non-random behaviour. We find that PSR J1819–1458 and PSR J1317–5759 emit more doublets (two consecutive pulses) and triplets (three consecutive pulses) than is expected in random pulse distributions. No evidence for such an excess is found for the other RRATs. There are several different models for RRAT emission depending on both extrinsic and intrinsic factors which are consistent with these properties.

Key words: stars: neutron – pulsars: general – Galaxy: stellar content.

1 INTRODUCTION

Rotating radio transients (RRATs) are neutron stars which were discovered only through their isolated pulses (McLaughlin et al. 2006). Some, however, have later been detectable through periodicity searches. The average intervals between detected pulses range from a few minutes to a few hours, and pulses have durations between 2 and 30 ms. Thus far, ~50 RRATs have been identified (Hessels et al. 2008; Deneva et al. 2009; Keane et al. 2010, 2011; Burke-Spolaor & Bailes 2010; Burke-Spolaor et al. 2011), including the original 11 from McLaughlin et al. (2006). Periods ranging from 0.1 to 8 s have been measured for 29 of these sources. Period derivatives have been measured for 14, allowing inference of spin-down properties such as characteristic ages and surface dipole magnetic fields (Lyne et al. 2009; McLaughlin et al. 2009; Keane et al. 2011). The periods and magnetic fields of RRATs are larger than those of normal pulsars, but the distributions of other spin-down properties such as spin-down energy loss rate and characteristic age are similar (McLaughlin et al. 2009). Despite this overall trend, the properties of individual RRATs vary considerably. Four RRATs, including PSR J1826–1419 and PSR J1913+1330, have spin-down properties consistent with the bulk of the normal radio pulsar population and two others, PSR J1317–5759 and PSR J1444–6026, have properties similar to normal, older pulsars. Four others, PSR J1652–4406, PSR J1707–4417, PSR J1807–2557 and PSR J1840–1419, lie just above the radio ‘death-line’ (e.g. Chen & Ruderman 1993; Zhang, Gil & Dyks 2007). However, some have more unusual spin-down properties. PSR J0847–4316, PSR J1846–0257 and PSR J1854–0306 lie in an empty region of spin-down space between the normal radio pulsars and isolated neutron stars (XINS), and PSR J1819–1458 has a high magnetic field of $5 \times 10^{13}$ G.

Because of the difficulties in detecting these sporadic objects, the total Galactic population of RRATs likely outnumbers that of normal radio pulsars (McLaughlin et al. 2006), though it is possible that the populations are evolutionarily related (Keane & Kramer 2008). Several ideas have been presented about the nature of the emission from these objects. It could be similar to that responsible...

for the ‘giant pulses’ observed from some pulsars (e.g. Knight et al. 2006). It could also be that the sporadic emission is related to the fact that these objects are near the radio ‘death-line’ (e.g. Chen & Ruderman 1993; Zhang et al. 2007) and/or are examples of extreme nulling (e.g. Redman & Rankin 2009). The phenomenon has also been attributed to the presence of a circumstellar asteroid belt (Li 2006; Cordes & Shannon 2008) or a radiation belt as seen in planetary magnetospheres (Luo & Melrose 2007), or, perhaps, some are transient X-ray magnetars (e.g. Woods et al. 2005). Another idea is that their properties lie at the extreme end of the population of normal radio pulsars. Weltevrede et al. (2006) show that PSR B0656+14, a nearby middle-aged pulsar which emits pulses with energies many times its mean pulse energy, would be discovered as an RRAT source if it were farther away. RRATs may also be considered as an extreme case of mode changing (see e.g. Wang, Manchester & Johnston 2007) where the on-state is less than or about one pulse period. Furthermore, Lyne et al. (2010) have recently shown that many pulsars exhibit a two-state phenomenon in which varying pulse profile shapes are correlated with variations in spin-down rates and implied changes in magnetospheric particle density. These changes are quasi-periodic, with time-scales ranging from one month to many years. It could be that the RRATs are similar two-state systems, in which the profile changes are so dramatic to make them undetectable in the more common state.

Determining the time variability and/or periodicity of the RRAT pulses is therefore an important diagnostic of the RRAT emission mechanism. While the pulse profile and, in most cases, pulse intensity changes of Lyne et al. (2010) are quasi-periodic, the pulse intensity distributions of normal pulsars and giant-pulsing pulsars are believed to be random over time. On the other hand, nulling pulsars in general show on and off time-scales of more than one consecutive pulse, indicating largely non-random distributions (see e.g. Redman & Rankin 2009). Radio-emitting neutron stars often show transient spin-down phenomena as well. For instance, glitches, or sudden increases in the spin frequency, have been observed from young pulsars and one RRAT (PSR J1819–1458). One of the glitches from PSR J1819–1458 was accompanied by a $3.5\sigma$ increase in the pulse detection rate (Lyne et al. 2009). Radiative events do not normally accompany the glitches of normal radio pulsars, but are quite common for magnetars (Dib, Kaspi & Gavriil 2008a). This, along with the high magnetic field of PSR J1819–1458, hints at a relationship with magnetars and also provides additional motivation to examine the pulse rate variations with time for all RRATs.

We search for periodicities and quantify the randomness of the detected RRAT pulses in several different ways. We first search for periodicities in the pulse arrival times on minutes- to year-long time-scales and pulse detection rates on month- to year-long time-scales using a Lomb–Scargle analysis. We then quantify the randomness of the RRAT pulse arrival times using Kolmogorov–Smirnov (KS) tests on seconds- to year-long time-scales. The observations are described in Section 2, the methods and results in Section 3, and the conclusions and plans for future work in Section 4.

2 OBSERVATIONS

All eight sources discussed in this paper were discovered by McLaughlin et al. (2006) in a re-analysis of data from the Parkes Multibeam Pulsar Survey. We have ignored three of the original 11 RRATs as their pulse detection rates are too low to perform this analysis. The discovery data were taken between 1998 January and 2002 February and follow-up observations began in 2003 August and are ongoing using the 64-m Parkes telescope. Most of the observations used the central beam of the multibeam receiver with a central frequency of 1.4 GHz and a bandwidth of 256 MHz. A few observations used other frequencies; we ignore these in our analysis to ensure uniformity of pulse detection rates. The sources have been observed at between 27 and 89 epochs at 1.4 GHz, with each observation 0.5–2 h in duration (see Table 1).

One important consideration in our analysis is the influence of the interstellar medium on our observed pulses. For all of these sources, the predicted diffractive scintillation bandwidths at 1.4 GHz are less than 1 MHz (Cordes & Lazio 2002), making modulation due to diffractive scintillation unimportant. In Table 1, we list the predicted time-scales for refractive scintillation at our observing frequency of 1.4 GHz, estimated from the predicted diffractive scintillation time-scales and bandwidths from Cordes & Lazio (2002) (see e.g. Lorimer & Kramer 2005). These time-scales range from 21 to 197 d. However, the actual time-scales could vary significantly from those predicted. The predicted modulation indices due to refractive scintillation (Lorimer & Kramer 2005) range from 0.09 to 0.17, meaning these are expected to be relatively minor contributions to pulse rate variations.

3 ANALYSIS AND RESULTS

Pulse detection is performed by de-dispersing the data at the dispersion measure (DM) of the RRAT and at a DM of zero. Then pulses are searched for in both time series above a $5\sigma$ threshold using the
pulsar processing package sigproc.\textsuperscript{1} Pulses which are brighter at the DM of the RRAT are likely to be from the source. We inspect the pulses visually by checking for pulse shape and pulse phase consistency to be certain of their astrophysical nature. For some epochs which have large amounts of radio frequency interference, we applied the above procedure but with multiple trial DMs as described by McLaughlin et al. (2009). If more than one pulse is detected within an observation, a second check based on the known period of the source can be made by requiring that all pulses have arrival times which differ by integer multiples of the period. For the sources with phase-connected timing solutions, we check that the pulse arrival time is consistent with the solution. In Table 1, we list the number of epochs for which pulses were detected for all sources. In Table 3 we list the total number of pulses detected within the entire time-span of observations.

### 3.1 Periodicity search

The Lomb–Scargle test (Scargle 1982) is a statistical procedure for uncovering periodic signals hidden in noise. We use this technique in our analysis as our data are unevenly sampled, thereby making standard Fourier analysis difficult. The implementation we used (Numerical Recipes, see Press et al. 1986) utilizes a version of the periodogram with modifications by Scargle (1982) and Horne & Baliunas (1986). Applications of this test to radio pulsar data can be found in Bailes et al. (1997) and Kramer et al. (2006).

The Lomb–Scargle test reveals signals in the power spectral density distribution of a source, with the presence of a sinusoid of certain frequency indicated by a peak in the spectrum at that particular frequency. The trial frequencies at which the periodogram is evaluated are chosen to be a finite evenly spaced set. For a time series $X(t_i)$ with $N_0$ number of elements, where $i = 1, 2, \ldots, N_0$, the Scargle angular frequencies range from $\omega = 2\pi/T$ to $\pi N_0/T$ (or periods from $T$ to $2T/N_0$), where $T$ is the total time interval. The searched frequencies therefore range up to the Nyquist frequency.

\begin{equation}
N_i = -6.362 + 1.193 \times N_0 + 0.00098 \times N_0^2.
\end{equation}

The number of frequencies searched is obtained from the empirical formula (Horne & Baliunas 1986)

The likelihood of the existence of a signal or the level of significance is calculated as a detection threshold $Z_0$ (Scargle 1982):

\begin{equation}
Z_0 = -\ln \left[1 - (1 - p_o)^{1/N_i}\right].
\end{equation}

The false alarm probability $p_o$ is the probability that a peak of power $Z_0$ will occur in the absence of a periodic signal.

#### 3.1.1 Periodicity in pulse arrival times

We have searched for periodicities in the pulse arrival times. In order to do this, we have created a time series by accounting for all rotations of the pulsar during each observation and assigning a delta function (i.e. one for each detection and zero for each non-detection). We performed this search on the entire time-span of observations.

In the time series for the entire time-span of observations, we searched over ~1000000 periods spaced as outlined at the beginning of Section 3.1, ranging from ~25 min to 2300 d. Six RRATs, PSR J0847–4316, PSR J1317–5759, PSR J1754–30, PSR J1819–1458, PSR J1826–1419 and PSR J1913+1330, show significant periodicities in the arrival times on these timescales. The peaks of highest significance for PSR J0847–4316, PSR J1317–5759, PSR J1754–30, PSR J1826–1419 and PSR J1913+1330 are at 3.8, 1.6, 1.4, 3.6 and 11.3 h, respectively, while PSR J1819–1458 shows a long-term periodicity of 2102 d.

There are many other significant periods and harmonics for these RRATs, with eight, three, one, 13, 15 and eight independent (i.e. non-harmonically related) periodicities with significance greater than 99 per cent (2.5σ) for PSR J0847–4316, PSR J1317–5759, PSR J1754–30, PSR J1826–1419 and PSR J1913+1330, respectively (See Table 2). These periodicities range from hours to years. Because of the large number of detected periodicities, we do not list them all here.

\caption{Periodicity in the arrival time $P_2$ and the number of harmonics (nh) detected for each periodicity in the entire time series for the six RRATs. Only the most significant harmonic for each period with a significance larger than 99 per cent is given. The periodicities are listed in the order of their spectral powers. We required the ratio between integer multiples of periods to be less than 1.001 to be considered a harmonic.}
\end{table}

\textsuperscript{1} http://sigproc.sourceforge.net

© 2011 The Authors, MNRAS 417, 1871–1880

In order to determine the time dependence of the periodicities, we divided the time series to halves and quarters and performed the search again. For every RRAT, all periodicities detected in the full series were redetected in at least one-quarter subsection with lower significances. None of the periodicities was redetected in every quarter, though seven out of the eight non-harmonically related periodicities of PSR J1913+1330 were redetected in three of the quarter data sets. Similarly, five out of the 13 non-harmonically related periodicities of PSR J1819−1458 were redetected in three quarters with significances greater than 95 per cent. The rest were redetected in only one or two quadrants.

All detectable (i.e. within the searched range) non-harmonically related periodicities of PSR J1913+1330 were redetected in both halves of the data set. For the rest of the RRATs only about five (for PSR J1819−1458) to two (for PSR J1913+1330) independent periodicities were redetected in both halves. However, every periodicity was redetected in at least one-half section of the data set with lower significance. These results in general show that the periodicities persist throughout the entire time-span of observations.

In order to gauge the reality of the periodicities, we randomized the time series of detections and non-detections by placing the pulses randomly within the observation windows and repeating the analysis. We found no periodicities with significance greater than 30 per cent in any of these randomized time series, which suggests the periodicities found are real. Fig. 1 shows the power spectra for the pulse arrival times from the randomized time series for the eight RRATs.

3.1.2 Periodicities in daily pulse detection rates

We have also applied this method to look for periodicities in the daily pulse detection rates. For each day, the observation length and the number of detected pulses were used to calculate the rate of pulse detection. Fig. 2 shows how this rate varies for the eight RRATs. We then applied the Lomb–Scargle analysis to these rates, with the results of this analysis shown in Fig. 3. We list the most significant period in Table 1 along with its significance.

We have performed white noise simulations and Monte Carlo simulations to verify the significance of the periodicities. In white noise simulations, the daily rates were replaced by random Gaussian noise. We could then calculate the power spectrum amplitude corresponding to the desired false alarm probability. In the second method Monte Carlo simulations were used to generate spectra from random time series which have the same sampling, and the cumulative probability distribution of their maximum amplitude is calculated. We then fit this distribution to equation (2), minimizing $\chi^2$ to determine an effective value for $N_i$ as this determines the false alarm probability for a given power spectral density. These tests verified the significances that we have quoted.

PSR J1819−1458 and PSR J1754−30 have periodicities with greater than 2σ significance at 1260 and 994 d, respectively. Both have periodicities with greater than 2σ significance at 1260 and 994 d, respectively. The remaining four RRATs do not show a periodicity of significance greater than the 1σ level. The significances obtained for the peak power spectral density for PSR J1819−1458 and PSR J1754−30 from white noise simulations are 97 and 96 per cent, respectively. The significances calculated from Monte Carlo simulations are 97 and 89 per cent. These periodicities are different from the ones detected in their pulse arrival times except for the 1260 ± 386 d periodicity of PSR J1819−1458, which is close to the pulse arrival time periodicity of 1186 ± 7 d. In general, the pulse arrival time and pulse rate recurrence periodicities are expected to be independent though it is possible for them to be the same.

In order to further gauge the reliability of our results for PSR J1819−1458 and PSR J1754−30, we created 1000 random sequences by assigning the measured pulse detection rates to randomly selected MJDs and calculated the number of times a peak of the same or higher significance appeared in the 1000 trials. This number was six and 10 for PSR J1819−1458 and PSR J1754−30, respectively, suggesting that the periodicities detected are real and that their significances may in fact be underestimated. However, the detected periodicities are at 40 and 50 per cent of the total observations lengths for PSR J1754−30 and PSR J1819−1458, respectively (see Table 1); longer observation spans are necessary to determine whether they are real. We also note that the significance of the peaks depends on the ranges of frequencies searched and that we have not searched frequencies higher than the Nyquist frequency or lower than 1/|T|.

In order to determine whether there was any dependence of significance on period, we simulated sinusoidal signals of various periods with additive random Gaussian noise and then applied the Lomb–Scargle algorithm. We found that the significance of the detected periodicities is independent of period.

3.2 Randomness tests on pulse arrival times

The KS test (see e.g. Press et al. 1986) is a statistical procedure which determines the degree to which two data sets differ. It compares the cumulative probability distributions of both data sets by calculating the maximum deviation,

$$D = \max_{-\infty < x < \infty} |C_1(x) - C_2(x)|,$$

(3)

of cumulative distribution functions $C_1$ and $C_2$. The accuracy of this test increases with the number of data points and is expected to be accurate for four or more points (Stephens 1970). From this the probability that two arrays of data values are drawn from the same distribution can be calculated. Small values of this probability (i.e. large values of $D$) suggest that the distributions being tested differ.

The test can therefore be used to explore whether the observed pulse sequences are consistent with random (i.e. Poisson) distributions. We have done this both by comparing the CDF of our data with the CDF of a simulated randomly distributed pulse sequence (i.e. kstwo test as implemented in Numerical Recipes) and by comparing the CDF of our data directly with the uniform CDF (i.e. kstwo test). We have performed this test both for single days and for the entire time-span of observations. For each single data set, we created simulated distributions by placing the same number of detected pulses at random times within the observation, with the constraint of allowing only one detected pulse per rotation. We also tested randomness on longer time-spans by creating random time sequences of length equal to the total observation length.

In Table 3, we list the total number of pulses observed from each RRAT along with the numbers of pulses detected on individual days. We also list the probabilities of the pulse sequences being random on a single day, averaged over all days of observation by comparing with simulated random pulse sequences and directly with a uniform CDF. The simulated probabilities on each day are averages of 100 000 trials of different randomly generated data sets. We also list the rms deviations of the averages. Table 3 also lists the probability of pulses being randomly distributed on long data.
Figure 1. Power spectral density versus period from the Lomb–Scargle analysis on pulse arrival times for PSR J0847−4316, PSR J1317−5759, PSR J1444−6026, PSR J1754−30, PSR J1819−1458, PSR J1826−1419, PSR J1846−0257 and PSR J1913+1330 (left-hand panel) and the corresponding plots when the arrival times are randomized (right-hand panel). The randomized time series do not show significant peaks in the spectra. The dashed line represents the 99 per cent significance level. Note the different y-axis scales in the left- and right-hand panels.
spans for simulated data (again averaged over 100,000 realizations) and through comparison with a uniform CDF. Fig. 4 illustrates this comparison for two RRATs.

In general, the pulse distributions appear to be consistent with random (i.e. Poisson) distributions. For simulated data, the single-day pulse distributions have probabilities ranging from 0.09 (for PSR J1754−30) to 0.52 (for PSR J0847−4316) of being random when only days with more than two detections are considered. When days with more than three are considered the probabilities range from 0.16 (for PSR J1826−1419) to 0.53 (for PSR J0847−4316).

Figure 2. Daily pulse detection rate versus date for PSR J0847−4316, PSR J1317−5759, PSR J1444−6026, PSR J1754−30, PSR J1819−1458, PSR J1826−1419, PSR J1846−0257 and PSR J1913+1330.
Analysis of RRAT pulsar arrival times

Figure 3. Power spectral density versus period from the Lomb–Scargle analysis on daily pulse detection rates for PSR J0847−4316, PSR J1317−5759, PSR J1444−6026, PSR J1754−30, PSR J1819−1458, PSR J1826−1419, PSR J1846−0257 and PSR J1913+1330. The dashed line represents the 95 per cent significance level.

Table 3. Total observation time, total number of detected pulses, minimum, maximum, mean (with standard deviation in parentheses) of the number of pulses observed per day, average probability of short-term randomness from the simulations \( P_{r1} \), the rms of the average \( \sigma_1 \), average probability of long-term randomness from the simulations \( P_{r2} \), the rms of the average \( \sigma_2 \), average probability of short-term randomness from direct comparison with the uniform CDF \( P_{u1} \) and the average probability of long-term randomness from direct comparison with the uniform CDF \( P_{u2} \). The probabilities for the simulations were calculated for 100 trials. The duration of each observation was 30 min to 1 h on average; as can be seen from \( N_2 \) there was one very long observation for PSR J1819−1458. The days with less than three pulses detected have not been included in \( P_{r1} \) or the \( P_{u1} \) probability calculation. The numbers outside and inside parentheses for \( P_{r1} \), \( \sigma_1 \) and \( P_{u1} \) indicate those for days with more than two/three pulses detected.

indicating that the bias for small numbers of pulses is small (there are no epochs with three or more pulses for PSR J1754−30). When we compare directly with a uniform CDF, PSR J1826−1419 and PSR J1913+1330 show more evidence (i.e. probabilities of 0.05 and 0.06) for non-random pulse emission. PSR J1754−30 shows evidence for non-random behaviour in both tests. As this is the RRAT with the lowest overall pulse rate, however, the tests are not very accurate.

The total number of detected pulses from each source ranges from \(~40\) to \(~1100\), making our tests for randomness on long time-scales very sensitive. When long time-spans are considered, only PSR J1444−6026 and PSR J1846−0257 are consistent with random distributions. The probabilities given by using the kstone and kstwo tests are similar. This is not surprising given the large numbers of pulses. We have tested these analysis techniques on intervals between pulses and checked for their consistency with an exponential distribution. Both pulse arrival time and pulse interval tests give identical results as expected. Furthermore, we have searched for any correlation between the pulse intervals on different time-scales and have found none.

We explored the possibility of the telescope zenith angle at the time of the observation being responsible for variations in pulse...
Figure 4. CDF for data over the entire time-span of observations of PSR J1754−30 (an example of a non-random pulse sequence) and PSR J1444−6026 (an example of a random pulse sequence) compared with the CDF of a uniform distribution (dashed line). The figure also shows the point at which the KS statistic $D$ is measured (vertical dot-dashed line). Small values of $D$ imply that the distributions are similar to each other. It can be seen that the first plot differs significantly from a uniform distribution, whereas the second does not. The probabilities of randomness are 0.001 and 0.31 for PSR J1754−30 and PSR J1444−6026, respectively.

Table 4. Measured number $N_m$ of doublets, triplets, quadruplets versus the expected number $N_e$, probability of occurrences under an assumed Poisson distribution $P_p$ for eight RRATs and the mean duration of the on-state in units of the period. The expected numbers are the means of 1000 trials of randomly generated fake distributions.

detection rates, as the system temperature depends on this factor and to account for effects based on varying gain and spillover. The KS test was carried out on pulse sequences for lower and higher angles (i.e. angles less than and greater than 45°) for this purpose. These results indicate that there is little dependence of the detected rates on the zenith angle, with probabilities ranging from 0.31 (for PSR J1317−5759) to 0.49 (for PSR J1819−1458).

We have also searched for clustering of pulses. For all of the RRATs, the pulses usually occur singly with occasional consecutive pulses detected. We have measured the total number of doublets, triplets and quadruplets (i.e. instances of two, three and four consecutive pulses) and compared with the number of doublets, triplets and quadruplets found in simulated random distributions. Table 4 lists the results of our analysis for 1000 simulated distributions. The number of doublets detected is higher than the number expected for a random distribution for both PSR J1819−1458 and PSR J1317−5759. PSR J1819−1458 shows many more doublets, triplets and quadruplets than expected, with one instance of nine consecutive pulses. The mean durations of the on-states (at which pulses are detected) for the eight RRATs in units of the period are also listed in Table 4. These were calculated by taking into account the number of detected multiplets and their duration. For the RRATs which do not exhibit multiplets, we can only give an upper limit to the on-state duration of one period as the mean on-state will be less than one period.

4 DISCUSSION

We have shown that six of the RRATs have periodicities of significance greater than 99 per cent in the pulse arrival times. The periods of the most significant peak range from 1.4 h (for PSR J1754−30) to 2102 d (for PSR J1819−1458). No significant periodicities were detected upon randomizing the time series, showing that these periodicities are real. We do not find any relationship between the number and significance of detected periodicities and spin-down properties such as period or characteristic age. It is possible that...
some of the periodic behaviour is due to refractive scintillation. However, the number and wide range of time-scales of the periodicities are impossible to explain with refractive scintillation alone.

The shorter time-scale periodicities in pulse arrival times are similar to typically observed nulling time-scales, which range from minutes to days (Wang et al. 2007). Explanations for pulsar nulling include an empty sightline passing through the sub-beam structure (Deshpande & Rankin 2001), a reversal of the emission direction (Melikidze & Gil 2006), pulsar emission ceasing temporarily due to intermittent failure of pair production (Zhang et al. 2007), an asteroid belt of material (Cordes & Shannon 2008) or changes in magnetospheric currents (Wang et al. 2007; Lyne et al. 2010). Any combination of these could explain the extreme pulse-to-pulse variability of the RRATs and also the longer term periodicities.

The significant periodicities found in the RRAT pulse arrival times may suggest a relationship with pulsars whose spin-down rates and pulse shapes undergo periodic variations, with implied changes in magnetospheric particle density (Lyne et al. 2010). The prototype of this source class is B1931+24 (Kramer et al. 2006). The asteroid belt model of Cordes & Shannon (2008) attributes the 40-d on/off time-scale of this pulsar to an asteroid with eccentric 40-d orbit. It may be that the pulse-to-pulse variability of the RRATs is due to a similar process happening on very short time-scales. However, because the on-states of the RRATs are so short, it is impossible to measure period derivatives during the on- and off-states. It could also be that a similar process is causing the longer term periodicities in pulse arrival times.

If we apply the model of Cordes & Shannon (2008) to the RRATs, multiple asteroids of an asteroid belt could be responsible for the observed periodicities in the arrival times. This is consistent with the large rms timing residuals which range from 1.1 ms (for PSR J1819−1458) to 11.2 ms (for PSR J0847−4316) of these RRATs as an earth-sized asteroid would induce residuals of the order of 1 ms (Cordes & Shannon 2008). However, it is possible that much of these large residuals are due to pulse-to-pulse jitter, indicating that the true asteroid mass cannot be determined by the residuals only.

The periodic fluctuations in pulse arrival times could also be due to non-radial oscillations which drive different emission modes, as often seen in white dwarf stars (Rosen, McLaughlin & Thompson 2011). The fundamental oscillation periods for neutron stars are expected to be of the order of milliseconds (Reisenegger & Goldreich 1992) to seconds (McDermott, van Horn & Hansen 1988) for g modes. These are far too short to explain the multiple periodicities seen, but it is possible that we are observing the beat frequency between a non-radial oscillation period and that from a longer time-scale process like those observed in Lyne et al. (2010).

We also searched for periodicities in the daily pulse detection rates. Six of the RRATs do not show any significant periodicities in their daily pulse detection rates over time-scales of months to years. The exceptions are PSR J1819−1458, which exhibits a 1260-d period with a significance of 97 per cent, and PSR J1754−30, which exhibits a 994-d period with significance of 95 per cent. We detect a peak of higher significance only 0.6 and 1.0 per cent of the time in 1000 trials in which the rates were randomly assigned to the MJDs for PSR J1819−1458 and PSR J1754−30, respectively, suggesting that the significance of the peak may be underestimated by the Lomb–Scargle algorithm. Given the eight trials, if all of the RRATs had no periodicities, we would expect to find one periodicity with significance greater than 88 per cent. However, two RRATs with significances greater than 95 per cent are not expected. The predicted time-scales for refractive interstellar scintillation of 117 d for PSR J1819−1458 and 21 d for PSR J1754−30 are much smaller than the reported periodicities in pulse detection rates, indicating that these periodicities are not likely due to scintillation. However, these periodicities are roughly half of the total data span. Therefore, a longer time-span of observations is necessary to confirm them as significant.

There is evidence for changes in period derivative associated with changes in pulse detection rate for PSR J1819−1458 (Lyne et al. 2009). The peak in the rate immediately following the first (and largest) glitch at MJD 53926 (Lyne et al. 2009) hints at a correlation between glitches and emission properties. If confirmed in future glitches, this correlation might suggest a link with the magnetars, for which radiative changes often accompany glitches (e.g. Dib, Kaspi & Gavriil 2008b) or the class of mode changing pulsars whose period derivative undergoes quasi-periodic changes (Lyne et al. 2010).

All of the sources exhibit random pulse distributions on single days. This is similar to that observed for giant pulses (Knight et al. 2006). However, the pulses from the RRATs are wider than those of observed giant pulses, and the pulse amplitude distributions are different (McLaughlin et al. 2009; Miller & McLaughlin 2010). This therefore supports the idea of Weltrevrede et al. (2006), who suggest that the RRATs could be normal, but more distant pulsars, like B0656+14 which emits very bright, narrow pulses and a distribution of weaker, broader pulses.

Over longer time-spans, the pulse sequences of six of the RRATs show evidence for non-random behaviour. These same RRATs show significant periodicities in arrival times. The external influence from, e.g., an asteroid belt (Cordes & Shannon 2008) could explain this through uneven distributions of material. However, it is difficult to relate this long-term non-randomness to either normal or nulling pulsars as, to our knowledge, this has not been explored for either of these source classes. We do not find any obvious relationship between the randomness and derived spin-down properties such as age, period and surface dipole magnetic field.

Nulling pulsars tend to have on/off-states which persist over more than one pulse period (Wang et al. 2007), whereas the majority of the RRAT pulses occur singly, aside from a few pulses from PSR J1819−1458 and PSR J1317−5759. Redman & Rankin (2009) showed that the majority of pulsars null non-randomly, and several studies (e.g. Rankin & Wright 2008; Herfindel & Rankin 2009) have revealed periodicities in the null cycles for some pulsars. The RRATs have quite different properties in these respects, but because the nulls of some pulsars (e.g. B0834+06, B1612+07 and B2315+21; Redman & Rankin 2009) are random and single-pulse nulls are occasionally observed, we cannot exclude the possibility of the RRATs being an extreme case of nulling. This is supported by the similar ages and spin periods of many RRATs and nulling pulsars, and the strong correlation between nulling and pulsar age (Wang et al. 2007).

In summary, we detect highly significant periodicities in the arrival times of six of the RRATs. We detect no highly significant periodicities in the long-term pulse detection rates for the RRATs, although we find tentative periodicities for PSR J1819−1458 and PSR J1754−30. All of the RRATs show random behaviour on a single day, and most of the RRATs show non-random behaviour on long time-scales. Most of the RRATs emit pulses singly, but a few do show evidence for clustering of pulses. It is clear that there are periodicities in the pulse arrival times for these objects. The cause of these could be circumstellar material, non-radial oscillations or another process. Radio monitoring over longer time-spans and observations at other wavelengths may be useful to further understand the reasons for the RRATs’ unusual emission. More theoretical work
and further studies of the randomness of pulse emission in normal pulsars with different properties are also necessary.

ACKNOWLEDGMENTS

We thank Jeffrey Scargle for very useful suggestions. We thank all on the Parkes Multibeam Survey team for assistance with the Parkes radio observations. MAM, NTP and DRL are supported by a WV EPSCoR grant. Pulsar research at UBC is funded by an NSERC Discovery Grant. EFK is supported by the EU Framework 6 Marie Curie Early Stage Training programme under contract number MEST-CT-2005-19669 ‘ESTRELA’.
