ABSTRACT

Skeletal And Dental Changes
With The Acrylic Splint Herbst Appliance

Clemente Casellas

The skeletal and dental changes in response to acrylic splint Herbst appliance has not been studied extensively. The purpose of this study was to determine the amount of skeletal and dental cephalometric changes of Class II patients treated with acrylic splint Herbst appliance. The sample consisted of one experimental group and one control group. The experimental group consisted of lateral cephalometric radiographs of 22 patients who have been treated with acrylic splint Herbst from the files of the Department of Orthodontics, School of Dentistry, West Virginia University. The control group consisted of 22 cephalometric radiographs of Class II patients with no treatment, selected from the Case Western University Bolton-Brush Study, Cleveland Ohio. These patients were matched in sex, age and craniofacial morphology with the experimental group subjects. The cephalometric system described by Pancherz was used to determine the cephalometric changes. An analysis of variance (ANOVA) was used to determine statistical significant differences. Significant differences in skeletal and dental changes were found in patients treated with the acrylic splint Herbst when compared with the control group. An overjet correction of 4.6 mm and a molar relation correction of 5.6 mm was obtained when compared to the control group. The study showed that 58.7% of the overjet correction was due to skeletal effects and 41.3% to dentoalveolar adaptations. Therefore it can be concluded that the dentoalveolar effects were due mainly to changes in the lower incisors. Whereas the skeletal effects were due to a combination of maxillary and mandibular structure changes.
DEDICATION

This thesis is dedicated to my wife and parents who have always encouraged and supported me.

A special thanks to the faculty, staff, and fellow residents who provided a wonderful environment in which to learn.
ACKNOWLEDGEMENTS

Special thanks are extended to the following individuals:

Dr. Peter Ngan for serving as a chairman of my committee and for his invaluable guidance, encouragement, and editing throughout this project.

Dr. Marcia Gladwin for her skillful editing abilities and guidance.

Dr. Jeff Gilmore for his advice and encouragement throughout this thesis.

Dr. Erdrogran Gunel for the statistical analysis of the data.

Case Western University Bolton-Brush Study (Cleveland, Ohio) for providing the records for this study.

CHAPTER I

INTRODUCTION

Class II malocclusion with mandibular deficiency can be treated using fixed or removable functional appliances. The Herbst appliance is a fixed functional appliance that has been shown to be effective in the treatment of Class II malocclusion. The original design of the Herbst appliance has orthodontic bands fitted on the premolars and molars. The bonded Herbst appliance was first proposed by Howe and McNamara (1982) and later evolved into the acrylic splint Herbst appliance\(^1\). The skeletal and dental changes associated with the banded Herbst appliance are well documented in the literature. However, there is a scarcity of literature on the changes associated with the acrylic splint Herbst appliance.

The aim of this study is to determine the amount of skeletal and dental cephalometric changes of Class II patients treated with acrylic splint Herbst appliance.

STATEMENT OF THE PROBLEM

The skeletal and dental changes in response to acrylic splint Herbst appliance has not been studied extensively. The objective of this study is to determine the cephalometric skeletal and dental changes of a group of Class II patients treated with the acrylic splint Herbst appliance.
SIGNIFICANCE OF THE PROBLEM

Fixed and banded Herbst appliance was used extensively in Europe for treatment of Class II division 1 malocclusion with mandibular deficiency. The acrylic splint Herbst appliance was introduced by McNamara in 1988 to provide additional anchorage for Class II correction\(^3\). The bonded appliance has the advantage of providing better anchorage by splinting the maxillary dentition together. However, it also suffers the disadvantage of having a removable lower member that requires patient compliance.

Results of this study will provide information on the skeletal and dental contribution to correction of Class II malocclusion using the acrylic splint Herbst appliance. Data can also be used in future studies to compare with those published using the fixed banded Herbst appliances.Clinicians can then decide on the advantage of using such appliance in the treatment of developing Class II malocclusion.
HYPOTHESIS

Two hypothesis from the basis study. They are:

1. There are no significant skeletal changes using cephalometric linear and angular measurements in patients treated with the acrylic splint Herbst appliance when compare with the control group.

2. There are no significant dental changes using cephalometric linear and angular measurements in patients treated with the acrylic splint Herbst appliance when compare with the control group.

DEFINITIONS OF TERMS

1. Maxillary expansion: Separation of the two halves of the maxilla achieved in the growing individual with the use of an orthopedic expansion device.²

2. Brachycephalic: Descriptive term utilized to describe the shape of an individual’s head as being more round, horizontally shorter, and broader.³

3. Dolichocephalic: Descriptive term which describes the
shape of an individual’s head as being horizontally long long and relatively narrow.³

4. Mesocephalic: Shape of an individual’s head, which is considered as being median between brachycephalic and dolichocephalic.³

5. Class II Malocclusion: That relationship in which the buccal groove of the mandibular first permanent molar articulates posteriorly to the mesiobuccal cusp of the maxillary first permanent molar. In other words, this represents a mesial relationship of the upper first molar to the lower first molar.³

6. Skeletal Class II Malocclusion: Skeletal relationship in which either the mandible is retrognathic, the maxilla is prognathic, or a combination of the two.³

7. Remodeling: A mechanically controlled activity that promotes tissue turnover throughout life.⁴

ASSUMPTIONS

This research is based upon three assumptions:
The lateral cephalograms are taken with the teeth in centric occlusion compromises the first assumption. It may be assumed that growth modification occurs in patients treated with the Herbst appliance.\textsuperscript{5,6,7}

Condylar remodeling take place in patients treated with the Herbst appliance comprises the third assumption.\textsuperscript{8}

\textbf{LIMITATIONS}

The following limitations may apply to the overall study:

1. This is a retrospective study with a group of patients selected from the files in the Department of Orthodontics, West Virginia University. The samples in the treatment and control groups are not selected at random.

2. The sample size was limited to the availability of patients and complete records.

3. The patient population has been selected from two different sources. (West Virginia University and Case Western University/Bolton-Brush Study Center)

\textbf{DELIMITATIONS}

The following delimitations may apply to the overall study.
1. Inclusion criteria for patient selection in the experimental group:

A) Female and male patients in mixed and early permanent dentitions that were diagnosed with Class II malocclusion with mandibular deficiency.

B) Patients that were treated with acrylic splint Herbst appliance with bonded upper member and removable lower member.

C) No previous orthodontic treatment.

D) The time between the pre and post-treatment cephalometric radiograph is limited to 12 months or less.

E) Availability of post-treatment cephalometric radiographs.

2. Exclusion criteria for patient selection in the experimental group:
A) Patients that are not cooperative in wearing the lower member of the Herbst appliance will be excluded from the study.

B) Patients with cephalograms taken more than 6 months after removal of the appliance will be excluded from the study.

3. Criteria for patient selection for the control group is limited to:

A) Female and male patients in mixed and early permanent dentitions with mandibular deficiency.

B) Patients that match the skeletal morphology of the experimental group in terms of angular and linear cephalometric measurements.
CHAPTER II

REVIEW OF THE LITERATURE

INCIDENCE

Class II malocclusion is a commonly observed clinical problem, occurring in about one third of the United States population\textsuperscript{9,10,11,12}. This classification of malocclusion seems to be more prevalent in individuals of Northern European ancestry (30%-40%) than in other racial and ethnic groups (14%-18% in blacks). Approximately eight to ten percent of the overall population have an overjet greater than six mm.

ETIOLOGY

The etiology of Class II malocclusion is multifactorial in nature. Skeletal orthodontic problems arise mainly as a result of an inherited pattern. In the United States, Class II malocclusion is due mainly to mandibular deficiency\textsuperscript{3}. Only a few types of Class II malocclusion are caused by specific interference with growth. There is little reason to believe that any significant number are the result of functional causes alone. This is not to say that functional alterations in equilibrium can’t accentuate Class II tendencies when they are present. The more severe cases probably fall into this category of inherited tendencies made worse by environmental effects\textsuperscript{3}.
COMPONENTS OF CLASS II MALOCCLUSION

According to Angle’s classification, Class II malocclusion occurs when the lower molar is distally positioned relative to the upper molar with the line of occlusion not specified. Angle based his classification system solely on the position of the permanent upper first molars. In reality, there can be numerous combinations of skeletal and dentoalveolar Class II malocclusions.

The different components of the Class II malocclusion have been described by Henry, Moyers et al and McNamara. Cross-sectional studies have shown that components of Class II malocclusion can be categorized into four main groups: anterior position of the maxilla, anterior position of the maxillary dentition, mandibular skeletal retrusion in absolute size or relative position, and excessive or deficient vertical development.

SKELETAL CLASS II GROWTH

Orientation of the facial bones can contribute to the Class II skeletal malocclusion. The bones in the cranial facial complex can be divided into several segments including the
anterior and posterior cranial base, nasomaxillary complex and the mandible\textsuperscript{28}.

**Cranial Base:** The primary growth in the cranium is through deposition on the outer cortex/resorption of the inner cortex and the sphenoid-occipital synchondrosis. The sphenoid-occipital synchondrosis is a major growth center and enlarges by endochondral growth. It also provides a bi-directional growth direction, which is described as a pressure adaptive mechanism that causes a displacement of bones\textsuperscript{28}.

Although Enlow states that the cranial base may lead to a downward and backward deflection of the mandible, creating a tendency towards a Class II malocclusion, no significant differences were found in a longitudinal study comparing the cranial base measurements between Class I and Class II individuals\textsuperscript{29}.

**Nasomaxillary Complex and Mandible:**

The growth of the maxilla occurs via bony apposition at the sutures between the cranium and the maxilla. The maxilla is displaced downward and forward away from the cranium. Exorbitant growth in either direction or an overall enlargement in the anterior posterior dimension may lead to a Class II skeletal pattern\textsuperscript{28}. In a cephalometric analysis
McNamara\textsuperscript{15} found that in Class II individuals, the position of the maxilla (SNA and A point perpendicular) is normal in majority of the cases. In other cases, the maxilla tended to be retrusive more than protrusive. Although a longitudinal study by Ngan et al, show no significant differences between Class I and Class II in the SNA angle, the last one tended to increase in Class I female subjects and decrease in Class II female subjects during growth spurt\textsuperscript{29}.

**Mandible:**

The mandible grows by deposition and resorption (remodeling). The predominant vectors (direction and magnitude) of growth are posterior and superior. Thus, the condyle grows directly toward its articular contact in the glenoid fossa of the cranial floor. As this take place, the whole mandible is moved forward and downward by the same amount that it grows upward and backward (displacement). The direction of growth by new bone additions at the condyle and the direction of displacement are opposite to each other\textsuperscript{29}.

The growth of the mandible may contribute to a Class II skeletal pattern by having a short corpus length, small ramus width, reduced ramus height or small gonial angle.
Canted occlusal plane can also play a role in the mandibular position. An occlusal plane that is canted inferiorly in the anterior will to a more retrognathically positioned mandible\textsuperscript{29}.

Bjork\textsuperscript{30} demonstrated several types of rotation in the mandible which can be used to predict different growth patterns of the mandible. They are defined as follows:

Type I: Axis of rotation is the condyle and the growth is upward. Normally seen in Class II division 2 cases.

Type II: Axis of rotation at the incisal edge causing downward rotational growth of the ramus and this leads to an increase in the posterior face height and shallow mandibular plane(Class II division 2).

Type III: Axis of rotation is a fulcrum point on the posterior teeth and this leads to a downward rotation of the posterior mandible and superior rotation of the anterior region. Increased posterior face height and decreased anterior face height are some of the features seen in Class II division 2.

Type IV: Axis of rotation is the center of the condyle. Rotation is down and backward. This leads to an increased
anterior face height which may be caused by bite opening devices (seen in prolonged intubation of young children) leading to a Class II division 1 pattern.

Type V: Axis of rotation is a fulcrum point in the posterior dentition and the rotation of the mandible is down and back leading to increased anterior face height and a retrognathic profile seen in Class II division 1 patterns.

**DIAGNOSIS OF CLASS II MALOCCLUSIONS**

A simplified method of evaluating patients by components according to the different planes of space assists in diagnosing the underlying cause of a Class II malocclusion.

1. **ANTEROPOSTERIOR COMPONENTS**

   Of critical importance is the soft tissue profile, particularly the nasolabial angle and the cant (slope) of the upper lip. Ideally, the nasolabial angle should be $102^\circ \pm 8^\circ$ in both boys and girls of Northern European ancestry (adults: $101^\circ \pm 12^\circ$ in males and $107.5^\circ \pm 7.5^\circ$ in females). In addition, the cant of the upper lip should be angled slightly in an anterioinferior direction ($8^\circ \pm 8^\circ$ in white males; $14^\circ \pm 8^\circ$ in white females relative to the nasion perpendicular).
The anteroposterior position of the bony maxilla is analyzed cephalometrically. Two cephalometric measures of anteroposterior maxillary position are nasion perpendicular to Point A\textsuperscript{33} and Sella-Nasion Point A (SNA) angle\textsuperscript{34,35}. The position of the maxilla is normal in the majority of Class II individuals and in those that the position of the maxilla is abnormal, the maxilla tends to be retrusive. Patients showing a long lower anterior facial height and steep mandibular plane angle often have both a maxilla and mandible that are retruded relative to cranial base structures.

When estimating the position of the upper incisors relative to the maxilla, the distance from the facial surface of the upper incisor to a vertical line drawn perpendicular to the Frankfort horizontal plane extended through Point A\textsuperscript{33} is recommended. In a well-balanced face, this measurement should be 4 to 6 mm\textsuperscript{33,36,2}. In Class II patients\textsuperscript{15}, almost half have a normally positioned upper incisor, 30% have a retrusive position and 20% have a protrusive position. A retruded incisor position represents an interference for Class II correction, especially when it involves the forward repositioning of the mandible (e.g., functional appliance therapy, mandibular advancement surgery) or retraction of the maxilla (e.g. extraoral traction, Le Fort I osteotomy).
The distance from the tip of the lower incisor to the A-Pogonion line\textsuperscript{37,38} can be used to determine the antero-posterior position of the lower incisor in relation to basal bone structures. Approximately two thirds of the Class II malocclusion have a normally positioned lower incisor.

To evaluate the mandibular skeletal position relative to the cranial base and cranial structures, two measurements can be used: Pogonion to the nasion perpendicular\textsuperscript{33} and Sella-Nasion-B point (SNB) angle\textsuperscript{34,35}. These measures indicate that a deficiency in the anterior-posterior position of the mandible is about 60% in the Class II malocclusion.

2. VERTICAL COMPONENTS
Although Class II malocclusion usually is perceived as a sagittal problem, the vertical dimension of the patient also must be considered. Especially since this dimension may either conceal or intensify the clinical appearance of the malocclusion.\textsuperscript{38-39}

A decreased in vertical dimension causes the mandible to rotate upward and forward. A patient with a short lower anterior facial height can camouflage a mandible that is structurally small relative to the midface. These patients
typically have a low mandibular plane angle, a deep overbite with a strong chin point, and either retruded or flared upper incisors.

A patient with an increased lower anterior facial height often is characterized by a retruded mandible (and occasionally the maxilla as well), a poorly defined chin point with a hyperactive mentalis muscle ("golf-ball" chin), and a tendency toward or an anterior open bite. A bump on the nasal contour ("dorsal hump") often is observed clinically in patients with both maxillary and mandibular skeletal retrusion and a Class II malocclusion.

To evaluate the vertical dimension, two measurements can be utilized. The mandible plane angle (MP-SN, MP-FH) and lower anterior facial height (anterior nasal spine to menton).

Although Class II patients most frequently have a neutral vertical dimension, about one third have excessive vertical development. Decreased vertical development is less common, occurring only in about 10% of the cases.

3. TRANSVERSE COMPONENTS

A dimension often overlooked in the evaluation of the Class II patient is the transverse relationship of the maxilla
to the mandible. Most Class II patients appear to have a normal relationship of the buccal segments when the patient is in centric occlusion. Tollaro et al,\textsuperscript{40} however, have shown that an underlying transverse discrepancy of three to five mm exists in dental arches with Class II malocclusion and seemingly normal buccal relationships. This underlying transverse discrepancy can be unmasked clinically by having the patient posture the mandible in an anterior position so that the canines are positioned in a Class I relationship. More significant transverse discrepancies are evidenced by unilateral or bilateral posterior crossbites in centric occlusion.

Studies by Baccetti et al\textsuperscript{41}, Arya et al\textsuperscript{42}, and Bishara et al\textsuperscript{43}, indicate that the Class II occlusal relationship tends to be self-perpetuating, and continues to be associated with a constricted transverse occlusal relationship.

Spillane\textsuperscript{44} and McNamara\textsuperscript{2} have recommended that in mild to moderate Class II patients with reasonably well balanced faces, orthopedic expansion of the maxilla through rapid maxillary expansion during the early mixed dentition is advisable. Not only will it create some additional arch space to allow for the eruption of the permanent incisors, but it
may also spontaneously correct the occlusal relationship by encouraging a transient forward mandibular posturing, in that the patient occludes more comfortably in a slight anterior position.

**TREATMENT OF CLASS II MALOCCLUSION**

Excluding surgical reposition of the jaws, there are four major possibilities for Class II correction:

I. Differential anteroposterior movement of the upper and lower posterior teeth as extraction spaces are closed.

II. Distal movement of maxillary posterior teeth.

III. Differential anteroposterior movement of all the teeth under the influence of Class II elastics.

IV. Differential growth of the jaws, guided by extraoral force or a functional appliance.

Although these approaches are not mutually exclusive and a combination is almost always used in treatment, the scope of this study is to focus on the last one.
I. There are two reasons for extracting teeth in the treatment of Class II malocclusion: (1) to provide space to align crowded incisors without creating excessive protrusion and (2) to allow camouflage of moderate Class II jaw relationships when correction by growth is not possible. Camouflage by extraction of upper first premolars and lower second premolars is a deceptively attractive solution to Class II problems although should be adopted only in specific cases.

II. Class II nonextraction treatment, which commonly includes distal movement of the maxillary molars to correct the molar relationship, most often can be successful when treatment is started in the late mixed dentition stage of development. At least two factors contribute to this success. One is that the molars can be distalized routinely at this age. The second is that the "E" space is available and can be used either to help correct the molar relationship or to resolve any crowding that may exist.45

III. Molar correction with Class II elastics, without extraction spaces, is produced largely by mesial movement of the mandibular arch, with a small amount of distal positioning of the maxillary arch. Large amount of force is usually required (approximately 300 gm per side) to displace one arch relative to the other when both are stabilized with

19
rectangular archwires. It is important to keep in mind that Class II elastics produce not only anteroposterior and transverse effects but also a vertical force. Class II are therefore contraindicated in nongrowing patients who can not tolerate some downward and backward rotation of the mandible. This is why Class II elastics are usually indicated for 3 to 4 months at the completion of treatment rather than using them for 9 to 12 months as the major method of correcting a Class II malocclusion.

IV. FUNCTIONAL APPLIANCE
HERBST THERAPY

The different timing of skeletal growth in males and females must be kept in mind (males pubertal peak: 13.9±1.0 yrs. and females pubertal peak: 11.7±1.0 yrs.) when using extraoral force or functional appliances to influence jaw growth. A favorable response of growth modification includes both restrain of maxillary growth and differential mandibular growth. Although the main purpose is to modify growth, some tooth movement in all three planes of space inevitably accompanies it.

Among the various types of orthopedic and functional appliances available today, the Herbst appliance is thought to be an effective device to correct Class II malocclusions.
In contrast to the removable functional appliances such as the activators, bionators, or Frankel appliance, the fixed Herbst appliance has several advantages: it works 24 hours a day, (2) no cooperation by the patient is required, and (3) active treatment time is short (6 to 12 months).

During the last 20 years, a number of clinical studies have evaluated the effects of the various types of Herbst appliances on the craniofacial skeleton. The banded type of Herbst appliance was developed by Emil Herbst in 1905 and was reintroduced by Pancherz in 1979. Both skeletal and dentoalveolar effects have been documented, regardless of the method of attachment of the Herbst mechanism to the dental arches [e.g., banded, cast splint, acrylic splint, and stainless steel crowns].

In 1988 McNamara and Howe described the current design of the acrylic splint Herbst appliance, with occlusal coverage extending posteriorly from the canines to the first molars in the maxillary arch and full occlusal coverage in the mandibular arch. The maxillary splint is either removable or bonded, whereas the mandibular splint always is removable.

Most previous investigators have reported only limited effects of the Herbst appliance on the maxillary complex. When
change in maxillary position (SNA) is evaluated, the forward
growth of maxilla relative to nasion is slightly less in
comparison with untreated controls$^{47,5,50,53}$.

Increases in the length of the mandible, ranging from
1.3 mm to 3.5 mm, have been documented in previous clinical
studies of the Herbst appliance in comparison with untreated
controls. Pancherz$^{47,54}$ found that the average increase in
mandibular length of 10 treated growing patients exceeded that
of 10 untreated growing subjects by 2.2 mm over a 6-month
period. A subsequent study by Pancherz$^5$ also showed an
additional 2.0 mm of length increase. In an investigation of
Headgear-Herbst treatment on a group of patients with severe
Class II malocclusions in the early mixed dentition,
Wieslander$^{48}$ reported that within a 5-month interval,
mandibular length increased 2.0 mm more in a treated group
than in an untreated control group. Valant and Sinclair$^{53}$
reported additional mandibular growth of 1.3 mm in a 10-month
treatment period. McNamara et al$^{49}$ reported an average of 2.7
mm more growth than in an untreated group, whereas Windmiller$^{50}$
reported an additional 3.5-mm of mandibular length increase.
Remodeling of the temporomandibular joint (TMJ) has been
described to occur both within the glenoid fossa and at the
mandibular condyles, with new bone formation occurring on the
roof of the fossa and on the posterior aspect of the condylar head\textsuperscript{55,8}. However, Croft et al\textsuperscript{,7} recently suggested that glenoid fossa displacement does not contribute in a clinically significant way to Class II correction. They also demonstrated with tomograms a tendency for the condyle to be slightly forward (0.2 mm) at the end of treatment and then to fall back after treatment. Instead, they found a significant redirection of condylar growth.

Previous studies have shown that Herbst appliance treatment typically has a bite opening effect. Pancherz\textsuperscript{47,5} observed an increase in lower anterior facial height produced by the banded Herbst appliance. In the investigation of treatment effects with the acrylic-splint Herbst, Both McNamara et al\textsuperscript{49} and Windmiller\textsuperscript{50} reported a significant increase in lower anterior facial height in the treatment groups. These studies did not show significant treatment effect on the mandibular plane, presumably because of an increase in ramus height posteriorly\textsuperscript{49,50}. In a study of vertical changes produced by different types of Herbst appliances, Schiavoni et al\textsuperscript{57} found the banded type as used by Panceherz did not modify the vertical growth pattern significantly, whereas the acrylic-splint type allowed an upward and forward rotation of the mandible.
In the dentoalveolar region, the Herbst bite jumping mechanism produces a posteriorly-directed force on the upper teeth and an anteriorly directed force on the lower teeth, resulting in distal tooth movement in the maxillary buccal segments and mesial tooth movements in the mandible. The mandibular incisors have been shown to procline during Herbst treatment\textsuperscript{47,5,53,56}. An Analysis of vertical dentoalveolar changes revealed that the upper first molars and lower incisors are inhibited from erupting during treatment\textsuperscript{5,49,53}, whereas the eruption of lower first molars is not affected significantly\textsuperscript{49,50,53}.

In summary the overjet and the Class II molar correction are a result of the following maxillary and mandibular skeletal and dental changes\textsuperscript{58}:

- Inhibition of maxillary growth
- Enhance of mandibular growth
- Distalization of maxillary buccal segments
- Proclination of mandibular incisors

Without proper retention, however, this effect is of a temporary nature. Herbst treatment is especially indicated in the permanent dentition at or just after the pubertal peak of growth. Mixed dentition treatment is not recommended, as a
stable cuspal interdigitation after therapy is difficult to achieve and relapses are prone to occur. In the nongrowing patient, the appliance should be used with great caution.58

The existing scientific data with respect to the short and long term effects of the Herbst appliance on the occlusion and on the maxillo/mandibular complex was analyzed by Pancherz, 6 months and 3.1 years posttreatment. During the first posttreatment period of 6 months, effective condylar growth recovered with respect to both the direction and the amount of changes. During the second posttreatment period of 2.5 years, effective condylar growth was “normal.” The corresponding chin position changes during the different examination periods were a mirror image of “effective condylar growth” (a summation of condylar remodeling, glenoid fossa remodeling, and condylar position changes within the fossa) when any mandibular autorotation occurred. In those cases with anterior mandibular autorotation, relatively more forward directed chin position changes resulted and in cases with posterior mandibular autorotation, relatively more backward directed chin position changes resulted.
CHAPTER III

METHODS AND MATERIALS

APPLIANCE DESIGN

The acrylic splint Herbst Appliance is composed of a wire framework, over which has been adapted 2.5-3.0 mm thick splint Biocryl. The posterior teeth are covered from the canines through the first molars in the maxillary arch, while full occlusal coverage is provided for the mandibular dental arch. The axels of the Herbst bite-jumping mechanism are soldered adjacent to the lower first premolars and the upper first molars (Fig.1).

SAMPLE DESCRIPTION

The research sample consists of a research and control group to test the two hypothesis presented.

I. Experimental Group: Twenty two patients treated with the acrylic splint Herbst were selected from the files of the Department of Orthodontics, School of Dentistry, West Virginia University.
Fig 1. Acrylic splint Herbst appliance: A, lateral aspect; B, frontal aspect.
The criteria of selection include:

1. Female and male patients in the mixed and early permanent dentition that were diagnosed with Class II malocclusion with mandibular deficiency.

2. Patients that were treated with acrylic splint Herbst Appliance with bonded upper member and removable lower member.

3. No previous orthodontic treatment

II. Control Group: Serial cephalometric radiographs of 22 Class II patients with no treatment were selected from the Case Western University Bolton-Brush Study, Cleveland Ohio. These patients were matched in sex, age and craniofacial morphology with the experimental group subjects. (Tables 1 and 2).

METHODOLOGY

IRB approval was obtained from the West Virginia University to use the cephalograms from the WVU Department of Orthodontics and the Bolton Brush Study. (Appendix A)

I. CEPHALOMETRIC ANALYSIS

The registration of the lateral cephalometric images were standardized as to magnification factor and completed on matte cephalometric acetate tracing film (3M Unitek, Monrovia, CA) with a 0.3 mm mechanical #2 HB lead pencil by one operator. The landmarks used are defined in Table 3. The reference lines used are defined in Table 4.

II. MEASURING PROCEDURE

The method of determining the sagittal and vertical movement achieved with the acrylic splint Herbst was modeled after the cephalometric systems described by Pancherz and illustrated in Figure 2.
Figure 2. The skeletal and dental cephalometric landmarks and reference lines (see Tables 3 and 4)
The reference grid utilized in this study was constructed from the occlusal plane (OL) and a vertical line perpendicular to the occlusal plane that passes through point Sella. Once constructed, this grid was transferred from the first cephalogram (T1) to the subsequent cephalogram (T2) by superimposing the tracings on the mid-sagittal cranial base structure. All linear measurements were performed parallel to OL and perpendicular to OLP. These measurements are listed in Tables 5 and 6. In addition to the linear measurements using the reference grid, three angular measurements were used with reference to the cranial base that are listed in Table 6.

STATISTICAL ANALYSIS

Data was analyzed using JMP statistical software on a MacIntosh computer. Intraclass Correlation Coefficient of Reliability was used to determine the reliability of the cephalometric measurements. The Reliability (R value) is a number between zero and one; where a R value greater than 0.90 indicates high reliability.

The control starting (T1) dentofacial morphology was matched to the experimental group (T1) by using a one-way analysis variance. One-way analysis of variance was also used to compare the treated and control group changes T1–T2. When the p-value is less than 0.05 (p<0.05) the difference between the control and experimental groups is declared significant.
CHAPTER IV
RESULTS AND DISCUSSION

RESULTS

This section presents the results and discussion of the effects of the acrylic splint Herbst therapy of 22 individuals treated in the West Virginia University. The results were compared to that of a matched control group according to age, sex, and pretreatment dentofacial morphology as illustrated in Tables 1 and 2.

Assessments of individual changes were made, and the arithmetic mean, standard deviations, minimum, and maximum values (millimeters and degrees) were calculated separately for the treated and control group (Tables 9, 10, 11 and 12).

The effects with the acrylic splint Herbst in the treated group were compared with the control group, and their differences were tested for statistical significance. The results are discussed in the following order:

I. Reliability of cephalometric measurements
II. Comparison of treated group vs. control group
III. Individual sagittal changes
IV. Individual vertical changes
V. Skeletal and dental contributions to the changes in overjet and molar relationship.
I. **Reliability of Cephalometric Measurements.** This section describes errors in location of landmarks, measurements, and superimposition performed by one examiner (intra-examiner error). The Intraclass Correlation Coefficient of Reliability (I.C.C.R.) for all sagittal, vertical and angular measurements were found to be greater than 0.9800, indicating that the measurements made are quite reliable (Table 7).

II. **Comparison of Treated vs. Control group.**

Treatment effects with the acrylic splint Herbst in the treated group were compared with the control group (Table 8 and 9). A two-tailed t-test (ANOVA) was used to determine statistical differences between the two groups. Statistical significant differences were found in 10 of the 18 variables measured.

For sagittal changes (Table 8), no significant differences were found in the upper incisor position (\(I_s/O_{lp}\)) and the mandibular base position (\(P_{g}/O_{lp}\)). Significant differences were found in the changes in overjet (\(I_s/O_{lp}-I_{i}/O_{lp}\)), lower incisors (\(I_{i}/O_{lp}\)), lower molars (\(M_s/O_{lp}\)), molar relation (\(M_s/O_{lp}-M_{i}/O_{lp}, p<0.001\)), upper molars (\(M_s/O_{lp}\)) (\(p<0.01\)), and maxillary base (\(A/O_{lp}, p<0.05\)).

III. Individual Sagittal Changes.

The individual sagittal cephalometrics changes of the control and treated groups are summarized in Tables 10 and 11, respectively.
Control group changes (Table 10). In most of the subjects, the overjet did not change or got worse. Only in four subjects did the overjet improved (cases #, 3,7,13 and 17). These improvements were of 1 mm with the exception of subject # 17, which improved by 3 mm. The mean change was an increase of 0.2 mm, with a variation ranging from -3 to 3 mm.

In the upper incisors there was a mean mesial movement of 1.9 mm, with a wide variation ranging from -10 to 5 mm. There was no consistent pattern found in these changes. In the lower incisors there was mean mesial movement of 1.8 mm, with a variation ranging from -9 to 2 mm.

The upper molar showed a mean mesial movement of 2.0 mm, with a variation ranging from -9 to 4 mm. The lower molar showed similar changes with a mean mesial movement of 1.9 mm and a variation that ranges from -9 to 3 mm. The molar relationship increase towards a Class II molar relation by 0.1 mm in average, with a variation ranging from -5 to 4 mm.

The maxillary base was increased in length in all the subjects except, in 3 subjects (# 1, 3 and 19). Cases 1 and 19 showed a decrease in length of 1 mm and # 3 decreased by 3 mm. The mean increase was 1.9 mm in average, with a variation ranging from -6 to 3 mm.
The mandibular base increase in length in all subjects except in 2 subjects (#3 and 19), they decreased by 3 and 1 mm respectively. The mean increase was 2.6 mm with a wide variation ranging from -13 to 4 mm.

Treated group changes (Table 11). A decrease in overjet correction was found in all subjects treated with the Herbst appliance, except subject no.4, in which there was a 1 mm increase in overjet. The average change in overjet correction was 4.4 mm and the variation in overjet changes were wide, ranging from -1 to 8 mm.

In general, the effect of the acrylic splint Herbst on the maxillary base was small with a mean increase in length of 0.4 mm. However the variation was wide, ranging from -4 mm to 7 mm.

There was a mandibular base length increase in all subjects except subjects #’s 4 and 10, in which the mandibular length decrease by 1 and 3 mm, respectively. The mean increase in mandibular base length was 3.8 mm, with a variation ranging from -10 to 3 mm.

The effect on the upper incisors was small with a mean mesial movement of 0.4 mm, but the variation was wide ranging from -4 to 6 mm. The lower incisors were found to move mesially with treatment in all subjects. The mean sagittal distance was large (-4.9mm) with a wide variation ranging from -1 to -10 mm.

Mesial movement of lower molars was found in all subjects except on subject # 16, in which there was no change. The average mesial movement was 5 mm with a range from -11 to
0 mm. Distal movement of upper molars was found to be 0.5 mm on average with a wide variation ranging from -7 to 8 mm. The molar relationship moved towards a Class I or Class III relationship in all the subjects. The mean movement was of 5.7 mm, with a variation ranging from 2 to 12 mm.

IV. Individual Vertical Changes.

The vertical cephalometric changes of the control and treated groups are shown in Tables 12 and 13.

Control group changes (Table 12). The maxillary base did not change significantly (-0.1 mm), but varied within a range of -3 to 3 mm. The lower facial height increased for all except two subjects (#’s 19 and 22), in which the lower facial height decrease was 2 and 1 mm, respectively. The mean increase reported was 0.8 mm, with a variation ranging from -4 to 2 mm.

The overbite was increased for all except 3 subjects (#’s 4, 11 and 21), and the increment was 1 mm for subjects #’s 4 and 21, and 2 mm for subject # 11. The mean overbite increased by 0.2 mm, with a variation ranging from -2 to 2 mm. Maxillary incisors exhibited no consistent pattern and there was not any significant change (0.1 mm). The variation ranged from -2 to 2 mm. Mandibular incisors extruded 0.8 mm in average, with a variation ranging from -4 to 1 mm.

Maxillary molars did not show any significant extrusion on average (0.1 mm), but a variation ranging from -3 to 2 mm was observed. Mandibular molars extruded by 0.5 mm, with a variation ranging from -7 to 3 mm.
Mandibular plane angle did not show any change on average (0.0 mm), but did show a variation ranging from -5 to 4 degrees. The occlusal plane and palatal plane did not change significantly (0.7 and 0.4 degrees, respectively) but did show variations ranging from -3 to 5 degrees and -4 to 6 degrees (respectively) for each.

Treatment changes (Table 13). The maxillary base change was small, with a mean downward movement value of 0.5 mm. and a range of -5 to 6 mm. The overbite reduction was found in all cases except on two subjects (#’s 13 and 18), in which there was a 1 mm increase in overbite. The mean value for the overbite correction was 2.5 mm, but the variation was wide, ranging from -1 to 7 mm.

The lower facial height was found to increase in most of the subjects. In three subjects (#’s 1, 11 and 13), the lower facial height was reduced. Lower molar eruption was enhanced by 1.1 mm with a variation ranging from -5 to 2 mm. Slight intrusion was found with upper molars (0.1 mm) with a variation ranging from -6 to 3 mm. Lower incisor intrusion of 0.2 mm was found with a variation ranging from -1 to 2 mm. Upper incisor extrusion of 0.7 mm was found with a variation ranging from -7 to 4 mm.

The changes in mandibular plane angle were minimal (-0.6 mm) with a variation ranging from -9 to 5 mm. The change in occlusal plane was in a counter-clockwise direction by 1.8 degrees with a wide range ranging from -13 to 10 degrees. The nasal plane angle was rotated in the same direction by 1.4 degrees with a variation ranging from -9 to 3 degrees.

V. Comparison of the skeletal and dental contributions to the correction of overjet and molar relationship.

After treatment, all subjects were corrected to a Class I or Class III dental relationship. The skeletal and dental contributions to the correction in overjet and molar
relationship are illustrated in Tables 3 and 4. The average overjet improvement in the treated group was of 4.4 mm; when growth is subtracted the total overjet correction was 4.6 mm. The contribution for the maxillary base, mandibular base, upper incisor and mandibular incisor was calculated in the same way. The calculations resulting in this contribution are listed in Table 14.

DISCUSSION

In general, the method of cephalometric analysis by Pancherz used in this study was reliable. The error of all variables was within an acceptable limit for the treatment changes (Table 7).

Sagittal changes. Statistical significant differences between the treated and control group were found in 6 of the 8 sagittal variables, as illustrated in Table 11.

Inhibition of maxillary growth relative to the cranial base was found to be statistically significant when compared with the control group at p<0.05 (Table 11). The maxilla only came forward an average of 0.4 mm compared to 1.9 mm in the control sample, a net restraint of 1.5 mm of forward growth. A similar headgear effect on the maxilla was also reported by the Wieslander 48 study. He observed 1.5 mm of posterior translation of “A” point with a headgear-Herbst Appliance for a period of 5 months. Croft et al 7 observed a 1.2 mm restraint of the maxilla. He used a crown Herbst for a period of 11 months. Valant and Sinclair 53 found a lesser headgear effect (0.7 mm) on the maxilla when a modified removable Herbst Appliance was used in their study.
Franchi, Bacceti and McNamara\textsuperscript{64} used an acrylic splint Herbst and found a mean increment in total mandibular length of 2.11 mm when compared with the untreated Class II controls after 28 months. Valant and Sinclair\textsuperscript{53} used a removable modified Herbst appliance, and found an increase in mandibular length of 1.3 mm over the control group. Although the mandibular length increase was found not to be statistically significant in this study, there was a net increase of 1.2 mm when compared to the control group.

Dental changes were also found with the bite jumping mechanism produced by the appliance. There was a posteriorly directed force on the upper teeth and an anteriorly directed force on the lower teeth, resulting in distal tooth movement in the maxillary buccal segments and mesial tooth movements in the mandible. This is in agreement with several other published studies. Distal tooth movement (1.0 mm) of the upper molars was significant (p<0.01). Croft \textit{et al}\textsuperscript{7} reported a maxillary distal tooth movement of 1.2 mm. The mesial movement of lower molars (1.9 mm) and incisors (1.9 mm) were highly significant (p<0.001) when compared to the control group in this study. Valant and Sinclair\textsuperscript{53} reported 1.6 mm mesial movement of the lower molars using the modified removable
Herbst. Mesial movement of lower incisor was reported by several investigations: Valant and Sinclair\textsuperscript{53} reported 1.0 mm, Franchi et al\textsuperscript{64} reported 1.4 mm and Pancherz\textsuperscript{47} reported 2.4 mm. The distal movement of upper incisors (0.0 mm) was not statistically significant at $p<0.05$. This is in agreement with most of the other Herbst studies, Franchi\textsuperscript{64} reported a distal tooth movement of 0.07 mm, Valant and Sinclair\textsuperscript{53} reported 0.2 mm and Pancherz\textsuperscript{47} reported a 0.5 mm distal movement of the upper incisors.

**Vertical changes.** In Class II patients with a deep bite, Pancherz showed an overbite reduction of 50\% immediately after treatment with the banded Herbst Appliance.\textsuperscript{54} Overbite reduction is mainly accomplished by intrusion of the lower incisors and enhanced eruption of the lower molars in his study. The author pointed out, that part of the vertical incisal changes were a result of proclination of the incisors. As a result, the occlusal plane tips downward.\textsuperscript{54}

The overbite reduction in this study was ($p<0.001$) significantly different between the experimental (2.5 mm) and the control group (-0.2 mm), which represents an overbite reduction of 2.7 mm. Lower incisor intrusion of 0.2 mm was also highly significant ($p<0.001$) when compared with the
control group (-0.8 mm). The eruption of lower molars (1.1 mm) was not significantly different from the control group (-0.5mm). Using the crown Herbst, Croft et al\(^7\) reported a significant (p<0.01) overbite correction (0.6 mm) with a difference of 2 mm when compared to the control group. Pancherz\(^47\) using the banded Herbst, reported a 2.5 mm correction with a difference of 2.6 mm when compared to the control group. Franchi et al\(^64\), Valant and Sinclair\(^53\), and Windmiller\(^50\) did not report the changes for overbite correction with the acrylic removable Herbst Appliance.

The mandibular plane angle was not changed significantly when compared to the control group. This could be due to an increase in ramal height during the treatment period as pointed out by McNamara\(^49\) and Windmiller\(^50\). The presence of an acrylic bite-block may help in controlling the eruption of molars and hence minimizing the opening of the mandibular plane angle.

The occlusal plane tipped clockwise 1.8 degrees, which was significantly different, compared to the control group (0.7 degrees counterclockwise, p<0.05). This is probably related to the differential eruption of the incisors and molars as a result of the treatment and the "bite-plane" effect.
Although the banded Herbst Appliance has been shown to increase vertical relationships, no change in the nasal plane angle in relation to the cranial base was noted in a study by Franchi et al. The nasal plane angle in the present study, showed a tipping of 1.4 degrees counterclockwise whereas the control showed a clockwise rotation of 0.4 degrees (Table 11). This is probably due to the headgear effect produced by the appliance.

Skeletal and dental contributions to the correction of overjet and molar relationship. The overjet correction in this study improved by 4.6 mm, which was significant at p<0.001. Franchi et al observed 3.99 mm of overjet correction (Acrylic splint Herbst), and Pancherz found a 5.2 mm overjet correction (banded Herbst).

The maxillary base contribution to this change was 32.6% (1.5 mm) less maxillary length increase, which was significant (p<0.05). This result that was two times larger (0.7 mm) than the one found by Valant and Sinclair. However, it was in perfect agreement with the findings reported by Weislander (1.5 mm), and a similar change was also reported by Croft et al (1.2 mm).
The mandibular base showed an increase in mandibular length of 26.1% (1.2mm), which was not significant at p<0.05. Valant and Sinclair\textsuperscript{53} showed a similar increase in mandibular length when compared to the control group (1.3 mm).

Mesial movement of the lower incisors was found highly significant in this study, representing 41.3% (1.9 mm) of the overjet contribution. Pancherz\textsuperscript{47} showed 1.8 mm of lower incisor mesial movement with the banded Herbst. Franchi et al\textsuperscript{64} observed 37.3% (1.7 mm) of incisor mesial movement with acrylic splint Herbst.

Distal movement of upper incisors did not show any significance in this study 0% (0.0 mm). Similar results were shown by Franchi et al\textsuperscript{64} (0.07 mm), Pancherz\textsuperscript{47} (0.5 mm), Valant and Sinclair\textsuperscript{53} (0.2 mm).

The molar relationship correction in this study improved significantly by 5.6 mm. Franchi et al\textsuperscript{64} observed a similar improvement of 5.38 mm. Mesial movement of lower molars was significant, showing 33.9% (1.9 mm) of the molar relation correction. Valant and Sinclair\textsuperscript{53}, on the other hand, reported
1.6 mm mesial movement of the lower molars when the modified removable Herbst was used.

Distal movement of the upper molar was significant (p<0.01) showing 17.9% of the molar relation correction (1.0 mm). Croft et al\textsuperscript{7} reported a 1.2 mm of molar distal movement using the crown Herbst whereas Valant and Sinclair\textsuperscript{53} obtained 1.5 mm using the modified removable Herbst.

Franchi et al\textsuperscript{64} reported that there is a greater skeletal contribution to the correction of both overjet and molar relation in subjects treated with the acrylic splint Herbst when compared with the results reported by Pancherz for a 6 month period of active treatment with the banded Herbst appliance. According to Franchi this is due to the smaller effect on the maxillary dentition and, more specifically to the minimal treatment effects on maxillary skeletal structures. This study did not show a lesser amount of dentoalveolar changes as a result of using the acrylic splint Herbst appliance. This is probably due to the significant headgear effect showed in this study.

The lower splint presumably helps to avoid proclination of lower incisors, although in this study the mesial movement
was significant. Franchi et al.\textsuperscript{64} showed that the mesial movement of the mandibular dentition represented the only significant dental change, and this movement contributed to the correction of both overjet and molar relation.

Clinical Implications

1. The acrylic Herbst with removable lower member has similar effects as the fixed Herbst.
2. For the overjet correction: the skeletal contribution was of 58.7\%, and the dental contribution was of 41.3\%.
3. For the molar correction: the skeletal contribution was of 48.2\%, and the dental contribution was of 51.8\%.
4. Because the acrylic Herbst Appliance has the advantage of a removable lower member, oral hygiene is easier to attain for the patient.
5. Since more teeth are anchored with the Acrylic Splint Herbst Appliance breakage is less likely to occur when compared to the other designs of the Herbst Appliance.

Future Studies

Other investigators have reported that there is a greater skeletal contribution in subjects treated with the acrylic splint Herbst when compared with the results reported with fixed Herbst Appliance. The results presented here, shows that
the acrylic splint Herbst Appliance has similar effects as the ones shown with the fixed Herbst Appliance. Further studies with longer-term effects, will be needed to corroborate these findings.
CHAPTER V

SUMMARY AND CONCLUSION

SUMMARY

The propose of this study was to determine the amount of skeletal and dental cephalometric changes of Class II patients treated with acrylic splint Herbst appliance.

The sample consisted of one experimental group and one control group. The experimental group consisted of lateral cephalometric radiographs of 22 patients who have been treated with acrylic splint Herbst from the files of the Department of Orthodontics, School of Dentistry, West Virginia University. The control group consisted of 22 cephalometric radiographs of Class II patients with no treatment, selected form the Case Western University Bolton-Brush Study, Cleveland Ohio. These patients were matched in sex, age and craniofacial morphology with the experimental group subjects.

The cephalometric system described by Pancherz\(^4\) was used in this study. An analysis of variance (ANOVA) was used to determine statistical significant differences.

The following hypotheses were to be tested at the completion of this research:
1. There are no significant skeletal changes using cephalometric linear and angular measurements in patients treated with the acrylic splint Herbst appliance when compared with the control group.

2. There are no significant dental changes using cephalometric linear and angular measurements in patients treated with the acrylic splint Herbst appliance when compared to the control group.

CONCLUSIONS

Six conclusions have resulted from this study. The first two conclusions address the hypotheses tested in this study. The remaining, conclusions are divided in two sections. The first section addresses the sagittal dimension (#’ 3 and 4), and the second section addresses the vertical dimension (#’s 5 and 6).

1. Statistical significant differences in skeletal changes were found in patients treated with the acrylic splint Herbst when compared with the control group.
2. Statistical significant differences in dental changes were found in patients treated with the acrylic splint Herbst when compared with the control group.

In the sagittal dimension:

3. In the skeletal region the inhibition of maxillary growth relative to the cranial base was found to be significant (headgear effect). A mandibular length increase of 1.2 mm when compared to the control group was found.

4. In the dentoalveolar region all the sagittal changes towards the correction of the Class II relationship were significant (lower incisor, overjet, upper and lower molars, and molar relationship), with the exception of distal movement of the upper incisor.

In the vertical dimension:

5. In the skeletal region the clockwise rotation of the nasal plane angle was statistically significant. Whereas the mandibular plane angle did not change significantly, probably the result of an increase in
ramus height. No significant changes were found in the maxillary base and lower facial height.

6. In the dentoalveolar region the overbite reduction and lower incisor intrusion was significant. The clockwise rotation of the occlusal plane angle was also significant. No significant changes were found for the upper incisors, upper molars and lower molars.

APPENDIX A

IRB Approval
Application for Exemption

You must receive approval from the IRB staff prior to beginning the research described below. Please type all responses and submit this form with original signatures.

1. Title of study: 

   Skeletal and Dental Changes of Patients Treated with Acrylic Speed Herb Apliances

2. Investigators (list all investigators, principal investigator first; attach additional sheets if necessary):

   Name  Signature       Dept./College  ORTHODONTICS  Phone No.
   Dr. Peter Nager
   Dr. Jeffrey Low
   Dr. Nancy Glad

3. Estimated period of human subject involvement: Starting date: June 1, 2000

4. Reason for conducting research

   □ Professional  □ Dissertation  □ Thesis
   □ Class Assignment  □ Other  □ specify

5. Source of funding (if applicable)

   Southern Association of Orthodontics, WVU University Health
   Associated

6. This research involves (check all that apply—see attached “Exempt Research” page):

   a. collection or study of existing data, documents, records or specimens, recorded without identifiers
   b. normal educational practices conducted in established or commonly accepted educational settings
   c. educational tests (cognitive, diagnostic, aptitude, achievement)
   d. observation of public behavior
   e. surveys, interviews or hand-outs for subjects over 18 (use age ranges, not actual age, for demographic information):
      □ mail  □ telephone  □ person-to-person
   f. any possibility of identifying a subject (discuss in cover letter)
   g. the possibility that the subject’s responses or conduct (if they became public) may place the subject at risk of criminal or civil liability or be damaging to the subject’s financial standing or employability
   h. sensitive aspects of personal behavior (for example: illegal conduct, drug use, sexual behavior or use of alcohol)
   i. investigator’s participation in activities being observed
   j. only surveys or interviews of elected or appointed public officials or candidates for public office
   k. audiotaping
   l. children under age 18 (see Chapter II of the Guidelines)
      Note: Interviews and surveys with children are never exempt
   m. food tasting and evaluation
   n. research and demonstration projects

7. Goal of research

   There is a need to determine the effect of Skeletal and Dental Changes of Patients Treated with Acrylic Speed Herb Apliances

   □ Research Study  □ Demonstration  □ Educational  □ Other

   □ specify

   □ tell

   □ similar
A cover letter addressed to respondents must accompany any survey or questionnaire. The cover letter must be on your 
WVU departmental letterhead and must include the following:

1. a statement that the project is research being conducted in partial fulfillment of the requirements for a 
course, master's thesis, dissertation, etc.
2. purpose of study
3. a statement that subjects' responses will be kept anonymous or confidential (explain extent of confiden- 
tiality if subjects' names are requested)
4. if audiotaping, a statement that subject is being audiotaped (explain how tapes will be stored or disposed 
of during and after the study)
5. a statement that subjects do not have to answer every question
6. a statement that subject's class standing, grades, or job status (or status on an athletic team, if applicable) 
will not be affected by refusal to participate or by withdrawal from the study
7. a statement that participation is voluntary
