ABSTRACT

NEST-SITE RESOURCES FOR CAVITY-NESTING BIRDS IN THE SOUTHERN ALLEGHENY MOUNTAIN FORESTS OF WEST VIRGINIA

HARRY A. KAHLER

Cavity-nesting birds may be negatively impacted by a lack of proper nesting sites. Southern Allegheny Mountain forests of West Virginia are unique due to the juxtaposition and diversity of forest cover types. Management must focus on monitoring wildlife population levels as well as habitat requirements within each cover type. Cavity tree abundance significantly differed among central hardwood ($\bar{x} = 16.4$; SE = 5.3), northern hardwood ($\bar{x} = 12.7$; SE = 6.8), and boreal forest cover types ($\bar{x} = 7.2$; SE = 3.6) ($P < 0.0001$). Black locust (*Robinia pseudoacacia*) and American beech (*Fagus grandifolia*) were most likely to have tree cavities, yet beech may be influenced by increased mortality from recent outbreaks of beech bark disease initiated by the beech scale insect (*Cryptococcus fagisuga*). Nesting bird community density, richness, and abundance do not differ among mature forests of the 3 cover types. Cavity-nesting species dependent on available tree holes were found most in the central hardwoods ($P = 0.009$). Forest managers should consider landscape level effects, as well as forest stand composition, when recommending silvicultural treatments.

This thesis dedicated to:

My daughter, Zelia Willow Kahler – that she may
come to know that she can accomplish anything through
perseverance and dedication.

Acknowledgements

I thank the following agencies for supporting this project: United States Fish and Wildlife Service, United States Department of Agriculture Forest Service, Sandpiper Technologies, and the McIntire-Stennis Program. I especially thank Karen Stevens and the rest of the personnel at the Greenbrier Ranger District of the U. S. Forest Service for cooperation, help, and advice.

I also thank the Mountain Institute for providing welcoming shelter on inclement nights. I thank Jason Calhoun, Sheri Helon, Todd J. Polesiak, and Karen A. Sacilotto for their field assistance. I especially thank Athena L. Kahler, who worked at least as long and as hard on this project as I did.

Additionally, I thank each of my committee members for their contributions to this project. I thank James Anderson, my major professor, for providing me the opportunity to further my interests with guidance and patience. I thank William Thayne for sharing his statistical knowledge. Lastly, I thank Ray R. Hicks and James Rentch for sharing invaluable experiences and advice about the forests of West Virginia.

CHAPTER 1

CAVITY-TREE SELECTION AMONG HOLE-NESTING BIRDS, A REVIEW

Abstract: Many challenges presently facing forest managers and ecologists stem from concerns, both real and imagined, that current forest management practices are oriented toward timber production and sales at the expense of wildlife habitat quality. One concern is that available nest-sites for cavity-nesting birds are reduced by intensive silviculture, thus negatively impacting avian reproductive efforts. Forests of the southern Allegheny Mountains of West Virginia are diverse in composition, mainly due to the topography of the region. Past forest management practices also have shaped the composition, structure, and size of forest patches within the region. Compared with other nesting strategies, cavity-use generally provides greater nesting success and decreased nest predation, yet adult longevity and fecundity rates vary among cavity-using strategies. Birds choose proper nesting sites based on cavity-, tree-, and habitat-level characteristics among forest stands. The importance of each characteristic varies with each nesting species. It is important to realize the habitat requirements of wildlife species when planning intensive forest management.

INTRODUCTION

Tree cavities have gained attention because the nest-site resource may be a

This thesis in the style of *Southeastern Naturalist*.

limiting factor to some dependent hole-nesting bird populations (Johnson and Kermott 1994, von Haartman 1957). An array of mammals and herpetiles also use tree cavities as denning, nesting, or food-cache sites (DeGraaf and Shigo 1985, Hunter 1990, McComb and Noble 1981). Most tree cavities are in standing dead or declining trees (Thomas et al. 1979).

Most obligate North American cavity-nesters are in the orders Passeriformes (songbirds), Piciformes (woodpeckers), Apodiformes (swifts), Coraciiformes (kingfishers), Strigiformes (owls), Psittaciformes (parrots), Anseriformes (waterfowl), and Trogoniformes (trogons) (Johnsgard 2000, Newton 1994). In total, dependent hole-nesters, or those that nest only in tree cavities, comprise 4% of the North American avifauna (Newton 1994). Cavity-nesting may have evolved as a means of increasing reproductive success relative to open-nesting (Martin 1995).

The forested landscape of the southern Allegheny Mountains in West Virginia is distinctive due to the diversity and juxtaposition of forest cover types. Boreal (i.e., red spruce [*Picea rubens*]), northern hardwood, and central hardwood forest types are all found within close proximity of one another (Buckelew and Hall 1994, Eyre 1980). Interestingly, similarities in North American coniferous forest vegetative diversity have been shown to decrease with increasing distance between forest patches (Nekola and White 1999). Thus, separation distances from similar cover also may affect wildlife species associated with the insular vegetative cover.

Additionally, southern Allegheny Mountain forests differ markedly in composition and size from those of times prior to settlement by Europeans (Hicks 1998). Habitat requirements differ for each wildlife species, yet diversity and abundances of

cavity-using wildlife may be suitable indicators of changes in forest stand conditions because of the close link between their reproductive success and the condition of forest resources (Carey 1983). For example, increases in snag (i.e., dead tree) densities generally correspond with increases in population densities, species richness and diversity of cavity-nesting birds (Zarnowitz and Manuwal 1985). Remnant snags (left after silvicultural treatment) provide suitable cavity sites for breeding birds (Ohmann et al. 1994). However, preservation of all cavity trees excessively reduce the total volume of harvestable timber (Goodwin and Balda 1983). Therefore, as is often the case, forests managers must strike a compromise when designating trees to leave or remove.

In view of the unique diversity of southern Allegheny Mountain forests, the purpose of this paper is to present the relationships between forest resources and avian cavity-nesting requirements. In particular, I review the advantages and costs of cavity-nesting in comparison with other nesting strategies. I also review forest and tree characteristics that may influence nest-site choices of cavity-nesting birds so that managers may be better posed to address wildlife habitat needs. Because forested landscapes are ever-changing, I begin with an overview of the recent past history of southern Allegheny Mountain forests.

FORESTS OF THE SOUTHERN ALLEGHENY MOUNTAINS REGION

The physiographic Allegheny Mountain section of the Appalachian Plateau runs southwesterly from central Pennsylvania to the highest peaks of West Virginia and Highland and Bath Counties, Virginia (Fenneman 1938). The southern portion of the Allegheny Mountains is generally included in the central hardwood region, which

contains 90% of the hardwood growing stock in the continental United States (Hicks 1998). More specifically, Braun (1950) regarded the southern Allegheny Mountains as part of the Mixed Mesophytic Forest Region of the central hardwoods, stressing the diversity of hardwood tree species found within the region. Because of these varying characteristics, the Allegheny Mountains contain vast, diverse, and unique forest lands.

The diversity of Allegheny Mountains forest types owes itself to the distinct topography of the area (Buckelew and Hall 1983, Hicks 1998). Slopes are steep, with reliefs mainly between 300 and 600 m (Hall 1983). At highest elevations, generally above 1000 m, forest types have boreal characteristics (Buckelew and Hall 1994). Moving down in elevation, forests become a mosaic between higher, north-facing northern hardwood types and lower, south-facing central hardwood stands (Hicks 1998). In effect, the boreal and northern hardwood forest patches of the Allegheny Mountains (and Southern Appalachians), which are relicts from colder eras, are analogous to islands separated from a mainland forest cover type (Hall 1983). In fact, Hall (1983) analyzed breeding bird data among these forest regions and found similarities to the island biogeography ideas of MacArthur and Wilson (1967) (i.e., the number of species inhabiting an island is inversely proportional to the distance from mainland).

When pioneering settlers came to West Virginia, most found slopes too steep for farming, yet level forests were cleared to establish some farmsteads (Clarkson 1993). At higher elevations, red spruce tracts were girdled and burned to produce cattle pastures and later logged for timber (Clarkson 1993, Stephenson and Adams 1993); only 10% of the original range of red spruce is now forested (Buckelew and Hall 1994).

Removal of the timber has left mostly a mosaic of second- and third-growth forests (Stephenson 1993). Where red spruce forests were removed by logging, much has been replaced by second growth, northern hardwood species (Stephenson 1993). Preferential harvesting of black walnut (*Juglans nigra*), butternut (*J. cinerea*), and white oak (*Quercus alba*) has resulted in proportionately fewer of these trees in present-day forests (Carvell 1986). European introduced diseases and pests, such as chestnut blight (*Endothia parasitica*), beech bark disease, and the gypsy moth (*Lymantria dispar*), also have changed stand composition over time (Acciavatti et al. 1993, Showalter 2000). Trees weakened by leaf stripping, such as those ravaged by gypsy moths, are then subject to attack by boring insects and wood rot from fungi (Sander et al. 1981, Showalter 2000).

Since the 1960s, boreal forests of North America have shrunk in area, mainly due to increasing mortality rates of red spruce and balsam fir (*Abies balsamea*) at higher elevations (Stephenson and Adams 1993). Allegheny Mountain spruce forest patches display this trend, coupled with declining growth rates of spruce trees, possibly from acid rain deposition (Stephenson and Adams 1993). Not only are numerous bird species of the Allegheny Mountains limited in breeding to the boreal forests (Hall 1983), but the entire populations of the federally endangered Virginia northern flying squirrel (*Glaucomys sabrinus fuscus*) and Cheat Mountain Salamander (*Plethodon nettingi*) are within these relict spruce forest patches (Green and Pauley 1987, Odom et al. 2001). A notable ecological relationship exists between Virginia northern flying squirrels and various hypogeous fungi taxa that have mycorrhizal links with spruce trees (Mitchell 2001). During spring and fall months the squirrels rely on these fungi for food, and in

turn are prime spore dispersers, thus contributing to the health of the spruce forests (Mitchell 2001).

Natural processes as well as management decisions are constantly changing forest cover composition and size. Undoubtedly, such changes continuously influence selection pressures that shape dependent wildlife population levels. Thus, knowledge of the life-history traits of cavity-nesting birds may supply a better understanding of the habitat characteristics required to maintain stable populations.

LIFE-HISTORY TRAITS OF AVIAN CAVITY-NESTERS

Generally, cavity-nesting birds may be divided into 2 groups: primary cavity-nesters that excavate nest-holes (chiefly woodpeckers), and secondary-cavity nesters that use available holes (Table 1). Skeletal and muscular specializations allow woodpeckers to excavate sound wood (Kirby 1980). Yet, some songbirds that may nest in available holes, particularly of the Paridae (chickadees) and Sittidae (nuthatches), also may excavate nest-holes if wood of advanced decay is available (Martin and Eadie 1999, Scott et al. 1977). Still, some primary-nesters, such as the yellow-bellied sapsucker (*Sphyrapicus varius*), may use cavities excavated by other species or re-use cavities in successive breeding seasons (Scott et al. 1977).

Because selection pressures may differ markedly between primary and secondary cavity-nesting species, sources and degrees of nestling mortality and other life-history traits also may differ between primary and secondary cavity-nesting species (Martin and Li 1992). For these reasons forest managers may find it easier to consider cavity resources as part of an ecological nest web, similar to a food web (Martin and Eadie

1999). A healthy nest web should include appropriate excavation trees for primary-nesters, as well as an adequate number of available and suitable holes for secondary-nesters.

To effectively provide nest sites for cavity-nesting birds, managers must understand why tree cavities are used. An examination of how life-history traits have evolved in cavity-nesting species in comparison to other species provides useful information on the suitability of tree cavities as nesting sites. The principle benefits of cavity-nesting in comparison to open nests include: lowered predation rates (Martin 1995, Nilsson 1986, von Haartman 1957); and increased protection from negative weather effects (i.e., deleterious temperature and precipitation levels) (Albano 1992; Slagsvold 1982, 1984). On the other hand, breeding success of cavity-nesters is limited by: increased parasite loads (Moller et al. 1990); inadequate cavity space (Slagsvold and Amundsen 1992, Stewart and Robertson 1999); and ill-suited microclimates within cavities (Wiebe 2001). In turn, all costs incurred by cavity nesting may increase as limitations to the nest web increase.

Early studies established the paradigm that hole-nesting species have greater nesting success than birds with open nests (Lack 1954, Nice 1957), particularly because cavity-nesters incur lower predation rates compared to open-nesters (Martin 1995, von Haartman 1957). Of North American cavity-nesting birds, woodpeckers have the highest rate of nest success (77%), followed by other primary species (i.e., weak – excavators) (66%), and secondary-users (54%) (Johnson and Kermott 1994). Martin (1995) analyzed the relationship between nest success, nest predation, and nest type (not using nest boxes) and determined primary excavators, followed by secondary cavity-nesters, have the

highest nest success and lowest predation rates of the 2 cavity-nest and 3 open-nest types studied. However, most early studies of nest predation were conducted on nest boxes, where predation rates may be lower than in natural cavities (Nilsson 1984, 1986). Indeed, when natural cavities were studied instead of boxes, Nilsson (1986) found the fledgling rate for 6 European secondary hole-nesters to be approximately equal that of open-nesters.

One notable nest-site characteristic that affects the nest success of secondary cavity-nesters more than primary cavity-nesters is the soundness of the surrounding wood (Albano 1992, Christman and Dhondt 1997). For example, Albano (1992) discovered that nests of Carolina chickadees (*Poecile carolinensis*) in softer wood were more likely to be depredated; in fact 78.7% of nest mortality was attributed to nest predation. Similarly, differences in wood soundness have been found between successful and depredated black-capped chickadee (*P. atricapilla*) nests; successful nests had significantly thicker walls and harder surrounding wood (Christman and Dhondt 1997).

In turn, other life-history traits are affected by nest-site characteristics (Martin 1995). For example, nest-site attributes and nest predation together explained over half (51.1%) of the variation in clutch sizes among 83 species of open-nesting (i.e., ground, shrub, and canopy) and cavity-nesting (i.e., primary and secondary) Passeriformes and Piciformes (Martin 1995). Adult survival, annual fecundity, broods per year, and clutch size also varies predictably with nest-site qualities (Martin 1995). Secondary-nesters were consistent outliers in nest predation relationships relative to other nest-site types, having larger clutch sizes and higher annual fecundity given their nest predation rates (Martin 1995).

Traditionally, food-limitation hypotheses have been widely accepted as accounting for the evolution of avian clutch sizes (Lack 1954). However, nest predation also had been suggested as the primary evolutionary determinant of avian clutch sizes (Skutch 1949). Naturally, females would lay a clutch size that maximizes their own individual recruitment (Pettifor et al. 1988), and clutch size is often smaller at nest sites with greater predation risks (Martin 1988).

Nur (1984) demonstrated that when brood sizes are artificially increased, parents actively choose not to maintain per capita feeding effort to maximize reproductive fitness. Lima (1987) developed a cost-benefit model in which females (of open- and cavity-nesting species) are able to control clutch size, foraging effort, and therefore nestling mass. The model indicated that clutch size may be food-influenced rather than food limited, and nest predation alone may be adequate to explain an existence of an optimal clutch size.

Although nest predation may be the driving force determining avian clutch sizes, other factors may influence clutch size in hole-nesting birds as well. For example, cavity size may affect clutch sizes laid by cavity-nesting birds (Stewart and Robertson 1999). Optimal clutch size may equate to the maximum number of nestlings that can fit in a nest cavity with the least cost to reproduction (Stewart and Robertson 1999). Indeed, clutch size is positively correlated with cavity size in several secondary-nesting species (Karlsson and Nilsson 1977, Rendell and Robertson 1993). By manipulating clutch sizes of tree swallows (*Tachycineta bicolor*) nesting in boxes of various sizes to the mode clutch size of 6 eggs, Stewart and Robertson (1999) determined that females may actively control clutch sizes to maximize their reproductive fitness. The effects of overcrowding

most logically explained growth differences between hatchlings in small and large nest boxes, which in turn translates into differences in reproductive fitness for the parents.

A third possible influence on clutch size of secondary cavity-nesters is nest-site availability (Martin and Li 1992). That secondary cavity-nesters have relatively larger clutch sizes and higher fecundity rates, given their predation rates (relative to other nest-site types), suggests that nest predation actually contributes little to secondary cavity-nesting species clutch sizes (Martin 1995). However, if nest sites are a limiting factor, then increased reproductive effort through increased clutch size are favored when suitable nest sites are obtained (Martin 1993).

In sum, life-history traits vary accordingly with nesting strategies. Primary cavity-nesting species, for example, usually have larger clutch sizes and greater nest success than other species, yet the cost is increased parental investment and lower reproduction rates. Accordingly, adult longevity is greater for primary cavity nesters. In contrast, secondary cavity-nesters invest relatively more energy in more broods/yr than other species, so reproduction rate is relatively high and adult longevity is relatively low. However, because nest-site quality varies among secondary cavity-nesting species, nest-success is relatively lower than primary-nesting species due to increased predation risks. Furthermore, Martin (1995) lumped weak excavating cavity-nesting species in with non-excavating species. Unquestionably, model results (relating nest strategies to life-history traits) were affected because weak excavating species have different selection pressures than true secondary cavity-nesters. Nonetheless, life-history traits undoubtedly drive nest-site choices in cavity-nesting birds.

FACTORS INFLUENCING NEST-SITE CHOICE

Interference competition, incorrect nest temperatures, and nest parasites are some examples of factors that negatively influence breeding success (Nilsson 1986). Predation also negatively affect breeding success (Albano 1992). Forest management practices influence these factors, and thus impact breeding success of cavity nesting birds. Hole-nesters increase success by choosing cavities that lessen negative impacts on breeding, and visual characteristics of forests and trees cue birds to suitable nesting sites.

Characteristics affecting cavity use occur at the cavity-, tree-, or habitat- level (Sedgwick and Knopf 1990). Because selection pressures are similar for species with identical nesting strategies, I do not limit examples to birds of the southern Allegheny Mountains.

Cavity-level Characteristics

Although the characteristics of individual trees may not be as indicative of wildlife use as forest stand characteristics, they are nonetheless important. For example, most birds tend to choose trees with little bark coverage (Land et al. 1989, Swallow et al. 1986). Likewise, primary cavity nesters appear limited by the hardness of some trees, which also will affect the numbers of secondary-nesting birds (Schepps 1999). Diversity and species richness tend to increase as the average snag height and amount of bark decrease, which is related to the advanced state of decay (Land et al. 1989). Some other indicators of wildlife use of cavity trees include fruiting bodies of heartwood decay fungi, branch stubs, and broken tops (Runde and Capen 1987).

Primary-nesting bird species choose cavities based on their structural quality (Harris 1983; McNair 1984). Cavity shapes formed by pileated woodpeckers (*Drycopus*

pileatus) followed decay patterns in the snag heartwood; the shape and soundness of surrounding wood determines usability as nest-sites (Harris 1983). Short (1979) suggests this behavior evolved as protection against cavity usurpation by larger or more aggressive cavity-users that would have to excavate harder wood to expand holes. This also is true of brown-headed nuthatches (*Sitta pusilla*), which in addition will plug crevices (in cavities) with bark shreds to make them usable (McNair 1984).

Secondary cavity-nesters reoccupy holes more frequently than primary cavity-nesters (Sedgwick 1997). Conner et al. (1998) suggested that male red-cockaded woodpeckers (*Picoides borealis*) select the newest cavities for nest sites due to increased ectoparasites in older cavities. Larval forms of Calliphorid flies (*Protocalliphora* spp.) found in some nest holes feed on the blood of nestling birds, decreasing fitness of the host birds (Whitworth and Bennet 1992). Additionally, many of the *Protocalliphora* are host specific (Bennet and Whitworth 1992), thus rendering otherwise suitable holes as deficient to some species. In response, male house wrens (*Troglodytes aedon*) remove old nesting material, increasing reproductive success by decreasing ectoparasite loads (Pacejka et al. 1998).

In southwest Virginia, Conner (1975) found significantly more woodpecker excavations leeward of prevailing winds to ameliorate negative microclimate effects. Similarly, northern spotted owls (*Strix occidentalis caurina*) on the Olympic Peninsula, Washington, occupy cavities oriented east-northeast, in avoidance of prevailing southwesterly storms (Forsman and Giese 1997). In contrast, excavations of northern flickers (*Colaptes auratus*) nest holes in British Columbia were biased toward the

increased warmth of the south (Wiebe 2001). Thus, climatic effects influence nest-site choice in cavity-using species.

Tree-level Characteristics

Runde and Capen (1987) found that yellow-bellied sapsuckers (*Sphyrapicus varius*) prefer nesting in quaking aspen (*Populus tremuloides*) with hard outer wood and older excavations. Kilham (1971) suggested that yellow-bellied sapsuckers seeking cavity sites have a search image of trees bearing false tinder (*Fomes igniarius* var. *populinus*) conks. Mature aspen, as well as butternut and American beech (*Fagus grandifolia*), bear such conks, which indicate soft heartwood inside harder, insulatory wood. Likewise, false tinder conks infected over 50% of cavity trees in Colorado montane aspen stands, which are out of yellow-bellied sapsucker range (Winternitz and Cahn 1983).

However, tree hardness is not necessarily related to external features such as number of conks or amount of bark present (Schepps et al. 1999). Weaker primary-users, such as the nuthatches, are more limited by soft wood availability than by abundance of large trees (Steege and Hitchcock 1998). Black-capped chickadees also are weak excavators and prefer soft outer wood (Runde and Capen 1987).

Excavation ability or strength is related to the morphology of the species (Kirby 1980, Schepps et al. 1999). However, in assessing hardness of trees used by red-naped sapsuckers (*Sphyrapicus nuchalis*), Williamson's sapsucker (*S. thyroideus*), hairy woodpeckers (*Picoides villosus*), and downy woodpeckers (*P. pubescens*), Schepps et al. (1999) found bird morphology an incorrect indicator of nest-tree usage. Sapsuckers are

assumed to be weaker than *Picoides* woodpeckers, yet red-naped sapsuckers nested in the hardest trees and downy woodpeckers chose the softest trees.

Damage to trees, such as bole injuries or broken tops, are indicators of possible chickadee and nuthatch nest trees (Runde and Capen 1987, Steeger and Hitchcock 1998). Tree damage can indicate to bird species wood softness due to disease, as red-breasted nuthatches (*Sitta canadensis*) preferentially use Douglas-firs infested with root disease (*Armillaria ostoyae*), stemwood decay, or mountain pine beetle infestation (*Dendroctonus ponderosae*) (Steeger and Hitchcock 1998).

Density of dead limbs, limb length, and tree diameter at 1.37 m (4.5 ft) (DBH) may drive nest-site choice among trees of preferred species (Sedgwick and Knopf 1990). One example of limb importance is that during incubation a male house wren will sing from a branch nearby the nest hole, possibly acting as sentinels for the nesting female (Ziolkowski et al. 1997). Some species, such as gilded flickers (*Colaptes chrysoides*), may prefer holes with unobstructed surveillance for potential predation (Zwartjes and Nordell 1998).

The general quality of the site also is important. The density and diversity of cavity nesting birds decreases with increasing understory thickness, possibly due to limited access to the snags (Brawn 1988, Land et al. 1989). At the same time, there must be enough understory vegetation at the nest site to provide protection from predators (Pogue and Schnell 1994, Rodewald and Smith 1998). Cavity nesting birds seem benefit most from small stands that are surrounded by a variety of forested land (Land et al. 1989). Trees that produce mast, such as American beech, should be managed as a food producer, even if they do not provide suitable cavities (McComb and Muller 1983).

Grubb and Bronson (1995) found that black-capped and Carolina chickadees use small diameter trees with hard surfaces, decreasing competition from larger nesters and reducing depredation. However, Runde and Capen (1987) found that black-capped chickadees prefer soft outer wood for excavation, and bark cover is not related to nest-site choice. In a southern Illinois study of Carolina chickadees, 78.7% of all egg and chick mortality was attributed to predation; nest-site selection plasticity and rapid renesting ability compensated for recruitment losses (Albano 1992). Albano (1992) found an inverse correlation between height above ground of chickadee nests and nest predation rates. In contrast, Hay and Guntert (1983) suggest that pygmy nuthatches select smaller and lower cavities to lessen convective heat loss from wind.

Habitat-level Characteristics

Red-headed woodpeckers prefer nesting in areas of high snag density, suggesting they require snags for foraging as well as roosting (Sedgwick and Knopf 1990). Ninety-six percent of variations in cavity-nesting bird density and diversity in slash pine (*Pinus elliotii*) plantations was explained by regressions on various stand and snag characteristics (Land et al. 1989). Snag clusters in the plantations were important indicators of where bird cavity nests were likely to occur.

In Kentucky, McComb and Muller (1983) determined black locust (*Robinia pseudoacacia*), flowering dogwood (*Cornus florida*), and sassafras (*Sassafras albidum*) were most prone to snag formation. Snag densities ≥ 10 cm DBH were greatest in stands dominated by chestnut oak (*Quercus prinus*) and red maple (*Acer rubrum*), yet red maple, American beech, and red oaks (*Quercus* spp.) showed reduced snag formation

(McComb and Muller 1983). Xeric areas exhibited higher snag densities than mesic sites (McComb and Muller 1983).

In general, when nest-site opportunities are more abundant woodpeckers nest more closely to one another than when nesting opportunities are scant, suggesting that quality nest-sites are a limiting factor directing habitat use (Short 1979). Similarly, black-capped chickadees and tufted titmice (*Baeolophus bicolor*) nesting near house wrens risk having nests, eggs, and nestlings destroyed (White and Kennedy 1997). White and Kennedy (1997) concluded nests in interior forest locations were less likely to be visited by house wrens than nests along forest edges.

Sedgwick and Knopf (1990) determined overstory decadence (measured by cavity density, snag density, total dead-limb length, and limb tree density) has a significant indicator of preferential nesting habitat to several cavity-nesting bird species in cottonwood floodplains. However, measures of basal area, canopy cover, density of medium-sized trees, openness, and distance to forest edge did not differ between bird nesting sites and random sites in the same area.

Swallow et al. (1986) concluded that overall forest-site characteristics influence primary-nesting bird uses as much as snag characteristics. Forest characteristics sampled included: type (i.e., second-growth or mature); species diversity and densities for tree, shrub, and herbaceous species; species diversity, density and basal area of snags; and average canopy closure. Snag characteristics included DBH, species, height, amount of remaining bark, twig or limb loss, fungal decomposition, and vine coverage. Also, a Missouri study of pileated woodpecker habitat indicated area covered by pole timber (15 - 25 cm DBH) was negatively related to bird abundance (Renken and Wiggers 1993).

MANAGEMENT CONSIDERATIONS

Because the forested landscape is not static, managers must be able to predict that outcomes of current management decisions will meet long-term, multiple-use goals. For example, forest fragmentation is recognized as a major negative impact on wildlife populations (Hagan et al. 1996). However, insular fragmentation effects that affect the biodiversity of southern Allegheny Mountain forests may result from natural phenomena. The natural processes and relationships of wildlife among various forest cover types should be analyzed and monitored on relatively unmanaged landscapes. Consequentially, the true outcomes of management decisions can be assessed with more accuracy.

Furthermore, wildlife density is not necessarily a good indicator of habitat quality (Vickery et al. 1992). In some cases, forest stands with greater wildlife population densities may have lower reproduction rates than forest stands with fewer individuals (Hagan et al., 1995). Reproduction rates for birds are most easily measured through nest surveys. Therefore, it is important to recognize suitable nesting sites for cavity-nesting birds for at least 3 reasons: (1) to predict or infer productivity rates based on nest-site quantities and quality, (2) to aid in nest searches for productivity monitoring (3) to judge impacts of current or proposed silvicultural activities on cavity-nesting species.

Sound forestry practices can include management for quality timber as well as for cavity-nesting birds. Generally, cavity trees are not likely to produce quality timber, yet many may be used multiple times by several animals (Carey 1983). However, because growing space is limited, compromises must be made when managing for wildlife and quality timber production. Thus, it is important to know which trees are most likely to harbor usable cavities so that management objectives can be maximized.

Table 1. Cavity-nesting breeding birds of the southern Allegheny Mountains region of West Virginia.

Common name	Scientific name	Cavity use ^a	General cover associations ^b
wood duck	<i>Aix sponsa</i>	obligate, secondary	wooded wetlands
hooded merganser	<i>Lophodytes cucullatus</i>	facultative, secondary	wooded wetlands
American kestrel	<i>Falco sparverius</i>	facultative, secondary	open areas, farmlands
barn owl	<i>Tyto alba</i>	facultative, secondary	semi-wooded areas
Eastern screech-owl	<i>Otus asio</i>	facultative, secondary	wooded areas
great horned owl	<i>Bubo virginianus</i>	facultative, secondary	mature deciduous forest
barred owl	<i>Strix varia</i>	facultative, secondary	mature mixed forests
Northern saw-whet owl	<i>Aegolius acadicus</i>	obligate, secondary	spruce or mixed forests
red-headed woodpecker	<i>Melanerpes erythrocephalus</i>	obligate, primary	open oak groves
red-bellied woodpecker	<i>Melanerpes carolinus</i>	obligate, primary	central hardwoods
yellow-bellied sapsucker	<i>Sphyrapicus varius</i>	obligate, primary	wooded, upper elevations
downy woodpecker	<i>Picoides pubescens</i>	obligate, primary	mixed forests
hairy woodpecker	<i>Picoides villosus</i>	obligate, primary	spruce or mixed forests
Northern flicker	<i>Colaptes auratus</i>	obligate, primary	semi-wooded areas
pileated woodpecker	<i>Dryocopus pileatus</i>	obligate, primary	mixed hardwoods
great-crested flycatcher	<i>Myiarchus crinitus</i>	obligate, secondary	mature central hardwoods
tree swallow	<i>Tachycineta bicolor</i>	obligate, secondary	flooded areas
black-capped chickadee	<i>Poecile atricapilla</i>	obligate, weak excavator	above 600m
Carolina chickadee	<i>Poecile carolinensis</i>	obligate, secondary	below 600m
tufted titmouse	<i>Baeolophus bicolor</i>	obligate, secondary	central hardwoods
red-breasted nuthatch	<i>Sitta canadensis</i>	obligate, weak excavator	spruce or mixed forests
white-breasted nuthatch	<i>Sitta carolinensis</i>	obligate, secondary	mature hardwoods
brown creeper	<i>Certhia americana</i>	facultative, secondary	mature forests above 750m
Carolina wren	<i>Thryothorus ludovicianus</i>	facultative, secondary	second-growth, brushy areas
house wren	<i>Troglodytes aedon</i>	obligate, secondary	farmlands, suburban lands
winter wren	<i>Troglodytes troglodytes</i>	facultative, secondary	spruce or mixed forests
Eastern bluebird	<i>Sialia sialis</i>	obligate, secondary	semi-wooded or open areas
European starling	<i>Sturnus vulgaris</i>	obligate, secondary	farmlands, suburban lands
house sparrow	<i>Passer domesticus</i>	facultative, secondary	farmlands, suburban lands

CHAPTER 2

TREE CAVITY RESOURCES FOR DEPENDENT CAVITY-USING WILDLIFE IN THE SOUTHERN ALLEGHENY MOUNTAINS

Abstract: Forestlands in the southern Allegheny Mountains are unique due to the diversity and size of forest cover. Relict patches of red spruce (*Picea rubens*), for example, provide habitat for entire breeding populations for cavity-using wildlife species such as the federally endangered Virginia northern flying squirrel (*Glaucomys sabrinus fuscus*), and outlying breeding grounds for bird species such as the red-breasted nuthatch (*Sitta canadensis*). The main objective of this study was to assess and compare tree cavity resources for dependent wildlife among various forest cover types of the southern Allegheny Mountain region. This study was conducted in the Greenbrier and Potomac Ranger Districts of the Monongahela National Forest, West Virginia. From fall 1999 through spring 2001, 25 50-m radius study plots were established in each of a central hardwood, a northern hardwood, and a boreal forest cover type; respective Society of American Foresters (SAF) forest cover types used were white oak – black oak – northern red oak (*Quercus alba* – *Q. velutina* – *Q. rubra*), black cherry – maple (*Prunus serotina* – *Acer* spp.), and red spruce – yellow birch (*Betula alleghaniensis*). Plot inventories were tallied with BAF 10 prisms, and entire plots were searched for cavity trees. Cavity tree abundance significantly differed among the 3 forest cover types ($P < 0.0001$), with highest cavity tree abundance in the central hardwood type ($\bar{x} = 16.4$; $SE = 5.3$), followed by the

This chapter is in the style of *Forest Science*.

northern hardwood type ($\bar{x} = 12.7$; SE = 6.8), and lastly the boreal type ($\bar{x} = 7.2$; SE = 3.6). Relative cavity likelihood was highest for black locust (*Robinia pseudoacacia*), followed by American beech (*Fagus grandifolia*), sugar maple (*A. saccharum*), and chestnut oak (*Q. prinus*). Black cherry and red spruce were least likely to harbor cavities. Abundance of excavated American beech cavities may be influenced by increased mortality from recent outbreaks of beech bark disease, initiated by the beech scale insect (*Cryptococcus fagisuga*). Biodiversity management of red spruce forests should consider numbers of large hardwoods, such as yellow birch, to provide cavity resources for dependent wildlife.

Additional Key words: Allegheny Mountains, cavity trees, relict forests, black locust, beech bark disease, Virginia northern flying squirrel.

A main challenge presently facing forest managers is harmonizing the various functions of multiple-use lands. One strategy commonly employed on public lands is ecosystem management, where managers strive to maintain desired ecological conditions while meeting other management objectives (Hicks 1998). However, ecological conditions will vary inherently with stand conditions, such as composition and age. For example, most cavities are in unhealthy or standing dead trees (i.e., snags) (Thomas et al. 1979, Davis 1983), and a variety of wildlife may use cavities as denning, nesting, or food-cache sites (McComb and Noble 1981, Davis 1983, Hunter 1990). Thus, tree cavity resources usually increase with stand age (tapering after about 100 years age for most forest types)

(Newton 1994). Clearly, baseline information is necessary for gauging cavity resource availability among forest stands.

Some bird species, such as woodpeckers (Piciformes), will create nesting sites (i.e., primary cavity-nesters), yet most other wildlife species rely on available holes in live or dead trees for nesting or denning (i.e., secondary cavity nesters)(Thomas et al. 1979, Martin and Eadie 1999). Many cavity trees serve multiple uses: Carey (1983) described a black walnut (*Juglans nigra*) tree used sequentially over a 32-month period by honey bees (*Apis mellifera*), a pileated woodpecker (*Drycopus pileatus*) foraging on carpenter ants (*Campanotus* sp.) followed by 2 northern flickers (*Colaptes auratus*) feeding in the recent excavations, a nursing gray squirrel (*Sciurus carolinensis*), a nursing fox squirrel (*S. niger*), another nursing gray squirrel, a denning opossum (*Didelphis virginiana*), and lastly a third gray squirrel brood. Tree cavities have gained attention because the nest-site resource can be a limiting factor to some dependent hole-nesting bird populations (von Haartman 1957, Zarnowitz and Manuwal 1985, Johnson and Kermott 1994).

Concerns about possible negative impacts of some forest management activities on cavity-tree resources have led to numerous publications relating cavity abundances to forest characteristics (i.e., cover types, stand features) and at times management practices (Newton 1994). Carey (1983) provides a useful evaluation of cavity-tree resources in hardwood stands of the Monongahela National Forest (MNF) of West Virginia. Carey (1983) found more cavities within oak – hickory (*Carya* spp.) stands than within maple - beech-birch stands. Carey (1983) concluded that random processes (e.g., natural pruning,

fire, wind, and ice damage) generated variation in cavity tree abundances rather than other stand or tree features (e.g., topography, tree diameters at breast height [DBH]).

Given the importance of snags as trees for cavity-using wildlife (Conner 1978, Davis 1983, Showalter 2000), much attention has been given to these forest components in particular. For example, in contrast to data from the MNF (Carey 1983), Rosenberg et al. (1988) found more and larger snags than expected in older stands (>100 years) of the Jefferson National Forest in southwest Virginia. Considering management effects, Graves et al. (2000) found snags 2.6 and 3 times more abundant on uncut stands than on areas thinned from below (i.e., by removal of suppressed and overtopped trees) to 45% and 60% residual stand density, respectively, in a West Virginia forest. Likewise, Moriarty and McComb (1983) found timber stand improvement (TSI) via girdling of poor quality trees reduced snag levels in hardwood stands of eastern Kentucky. Furthermore, Stribling et al. (1990) found bird community richness and abundance significantly higher on TSI plots with snags retained than on control TSI plots in central Pennsylvania. Such studies often elucidate detrimental effects on wildlife populations from removing poor quality and/or dead trees from forest stands.

However, assumptions that a dearth of snags limits cavity-dependent wildlife populations are not always valid. In the MNF, Carey (1983) found that 70% and 95% of cavity trees deemed usable by birds and mammals, respectively, were live. Similarly, Sedgwick and Knopf (1986) found 2.3 usable-cavity trees/ha, yet only 0.66 snags/ha in cottonwood bottomlands of east Colorado. More so, suitable cavities are not always limiting factors to secondary-nesting wildlife. For example, by manipulating cavity availabilities and counting breeding secondary-nesting bird densities within oak-pine

(*Pinus* sp.) study plots of central California, Waters et al. (1990) concluded that cavities were not limiting secondary-nesting breeding birds.

Generally, the Allegheny Mountains are considered within the central hardwoods region, yet northern hardwood and boreal forest types also can be found within the immediate area (Eyre, 1980; Hicks 1998). The physiographic Allegheny Mountain section of the Appalachian Plateau runs southwesterly from central Pennsylvania to the highest peaks of West Virginia (Fenneman 1938). At the highest elevations of the Allegheny Mountains in West Virginia, generally above 1000 m, relict patches of boreal forests remain from cooler, periglacial times (Hall 1983). Moving down in elevation, forests become a mosaic between higher, north-facing northern hardwood types and lower, south-facing central hardwood stands (Hicks 1998).

The diversity among forests of the southern Allegheny Mountains provides a unique possibility to examine tree cavity resources among various forest types. Whereas Carey (1983) described cavity properties among a range of stand ages in central hardwoods (i.e., oak-hickory forests) and northern hardwoods (i.e., birch-beech-maple forests), opportunity exists to provide baseline comparison data among hardwood types, as well as boreal forest types, by studying only mature stands. Therefore, the objectives of my study were to: 1) compare cavity abundances among mature stands of boreal, northern hardwood, and central hardwood forest types; 2) identify which tree species, if any, are important cavity-producing species; 3) identify characteristic differences between cavity trees and other trees within stands; 4) compare present cavity resource information with past information; and 5) assess management implications of all findings. Null hypotheses I tested were: 1) there is no difference in cavity abundance among forest

types, regardless of age, basal area, elevation, aspect, or slope of forest stands; 2) the likelihood of cavity abundance is equal among all tree species; 3) Cavity trees are no different than conspecifics in diameter and height.

STUDY AREA

The study was conducted on the Potomac and Greenbrier Ranger Districts of the MNF, in Pendleton, Pocahontas, and Randolph Counties, West Virginia. More than 80% of Randolph and Pocahontas Counties are forested, whereas wider valleys in Pendleton County account for slightly more farmland and less forest (Buckelew and Hall 1994). The logging industry began in the region after the civil war, and the arrival of railways in the 1880s allowed lumber to be harvested more quickly (Clarkson 1993). The slash left behind provided fuel for fire, which ravaged areas and removed the topsoil (Clarkson 1993). Subsequently, the loss of the forest was blamed for floods that occurred in the region during the early 1900s (Clarkson 1993). These events led to the formation of the MNF in 1920 to protect the forest resources in the southern Allegheny Mountains.

Based on the classification system of the Society of American Foresters (SAF), 9 of the 255 numbered North American cover types commonly occur throughout the southern Allegheny Mountains (Eyre 1980). The SAF forest cover types are identified by tree species that comprise the majority of stand stocking. Central hardwood forest types, generally referred to as oak-hickory forests by U.S. Forest Service terminology, include the SAF forest cover types: chestnut oak (SAF type 44); white oak – black oak – northern red oak (type 52), which includes the sub-type scarlet oak (*Q. coccinea*) – chestnut oak; white oak (type 53); yellow-poplar (type 57); and yellow poplar – white

oak – northern red oak (type 59) (Eyre 1980). Northern hardwoods, referred to by the U.S. Forest Service as maple – beech – birch forests, include SAF forest cover types: sugar maple (type 27); black cherry – maple (type 28), including both red and sugar maples; beech – sugar maple (type 60); and red maple (*Acer rubrum*) (type 108) (Eyre 1980). The relict sub-alpine stands are either classified as: red spruce (type 32) if the stands are pure (>80% red spruce); or red spruce – yellow birch (type 30) where these species together comprise the majority of the stocking (Eyre 1980).

Prevailing winds come from the west, creating the greatest amounts of precipitation along the upper-west slopes and a rain-shadow effect along east slopes (Buckelew and Hall 1994). Thus, annual precipitation is highest in Randolph County (> 132 cm/yr), somewhat lower in Pocahontas County (119.4–132 cm/yr), and lowest in Pendleton County (94–106.7 cm/yr) (Buckelew and Hall 1994). The average winter temperature in the western valley at Elkins, Randolph County is -1°C (31°F), and the average summer temperature is 19°C (67°F) with a maximum of 27°C (80°F) (Pyle et al. 1982). Interestingly, temperature averages in the eastern valley at Franklin, Pendleton County are 1°C (2°F) higher than the average temperatures in Elkins (Estepp 1992). Average temperatures along the Allegheny Mountain ridgeline are -8°C (18°F) in winter, and 19°C (66°F) in summer with a maximum of 24°C (76°F) (Estepp 1992).

All study plots were within 27 km (16.8 mi) of a geographic center near Lost Run in Highland County, Virginia, which is about 11.8 km (7.3 mi) east of the Greenbrier District Ranger Station in Bartow, West Virginia. Thus, many study plots were scattered among the Cheat and Middle Mountain ridgelines to the west of the Allegheny Mountain divide, and some were placed at lower elevations along the east slope of the main divide.

Elevation within this area is typical of the southern Allegheny Mountain region, ranging from about 540 m (1772 ft) to 1481 m (4861 ft) on Spruce Knob along the eastern divide in Pendleton County. However, relief usually ranges between 300 m (1000 ft) and 500 m (1600 ft) (Hall 1983). The terrain is hill-and-valley with some slopes near 70 % grade; the prevailing ridges and rivers generally follow a south-west to north-east alignment (Pyle 1982).

Soil types reflect topography, climate, parent material, living organisms, and time (Estepp 1992). There are about 20 general soil association types within the study area; study plots were located on 10 of these soil associations: Berks – Weikert, Dekalb – Berks – Calvin, Cateachie – Shouns – Belmont, Calvin – Shouns, Dekalb – Buchanan, Potomac – Tioga – Holly, Dekalb – Blackthorn – Elliber, Lehew – Hazleton, Mandy, and Calvin – Dekalb – Hazleton (Pyle 1982, Estepp 1992, Flegel 1999). Calvin – Shouns soils are often dominated by central hardwood tree species (Flegel 1999). Dekalb – Buchanan soils, found in the Shaver’s Fork drainage area in Randolph County, are generally productive yet may be subject to flooding (Pyle 1982). The widely ranging Berks – Weikert soils are often shallow, and are subject to drought and overgrazing on steep slopes (Estepp 1992, Flegel 1999). Mandy soils are almost exclusively within the MNF, and mainly produce sugar maple, or beech – maple stands (Flegel 1999). Cateachie soils, which typically produce sugar maple stands and mixed oaks at lower elevations, often present a slippage hazard due to steepness (Estepp 1992). Dekalb – Blackthorn – Elliber soils, occurring mainly on upper slopes in Pendleton County, are well suited to wood production (Estepp 1992).

Many specific soil types vary within each major association, and site indices were created for each soil type so that managers can predict tree growth on each location (Pyle 1982, Estepp 1992, Flegel 1999). Site indices vary widely throughout the study area, typically ranging from 35 to 80; values indicate the expected height of trees after 50 years growth (Pyle 1982, Estepp 1992, Flegel 1999).

METHODS

To analyze cavity resources among central hardwoods, northern hardwoods, and boreal forests of the southern Allegheny Mountains, I chose to focus on 1 SAF forest cover type in each general forest category so variations in stand compositions among categories could be minimized. I also used an arbitrary minimum stand age of 90 years so that only mature stands would be compared, yet a practical amount of usable stands would exist. I chose the white oak – black oak – northern red oak type as a central hardwood because each of these species is commercially important and common associates include most other central hardwood species. I also focused on black-cherry maple stands among northern hardwoods because of the current importance of black cherry veneer in timber markets. To reduce possible bias resulting from different species growth forms, I chose to focus on red spruce – yellow birch rather than pure red spruce as a boreal forest cover type.

Plot Establishment

I obtained a list of forest stands ≥ 90 years old on the Cheat/Potomac and Greenbrier Ranger Districts in September, 1999. The database lists stands, by

compartment, along with forest type, area, age, basal area, and management area. Forest service personnel advised me of about 20 compartments that contained high percentages of the SAF forest cover types upon which I was focusing my study. From these, I randomly selected appropriate stands in which to establish study plots. I avoided areas with recent or intense management activity, and areas more than 1200 m from a drivable road. Using compartment maps from the Forest Service, I selected a random distance and compass bearing from an access point to establish the center for each 50 m radius plot (0.78 ha). Each plot was within 1 mapped stand, and plots were at least 250 m apart for independent sampling (Ralph et al. 1995). I set up 25 plots in each SAF cover type for a total of 75 plots (Figure 1). All plots were established when leaves were absent from trees to facilitate cavity searching. Thirty plots (10 per forest type) were established by May 2000; all others were set up by May 2001.

Plot Inventory and Cavity Search

Plot UTM coordinates were determined from satellite signals received by a Trimble Global Positioning System (GPS) placed at each plot center. Center point slope and prevailing aspect were recorded (Marcot 1983, Marzluff and Lyon 1983). I determined plot elevations, mean daily maximum and minimum temperatures per year, and annual precipitation rates using geographic information systems (GIS) analysis; by overlaying center point location information on digital grid coverages (with cell sizes of 90 m) of West Virginia using ArcView GIS software. Coverages of elevation, temperature, and precipitation were provided by the West Virginia Natural Resources Analysis Center (West Virginia Natural Resources Analysis Center 2001). In summer

months I estimated percent overstory cover (codominant and dominant canopy), understory cover (<2 m tall to overtopped canopy), and shrub cover (<2 m tall) of each plot by averaging 4 measurements of each: estimates at center points and estimates at 3 random equidistant points about 25 m from the plot center.

I sampled center points via a prism with a basal area factor of 10 to determine basal area and tree tallies within plots. For each tallied tree the species, diameter at 1.5 m (DBH), and height (determined with a clinometer) were recorded. The health of each sampled tree also was recorded on a scale of 1-7, where 1 is a healthy codominant tree (Maser et al. 1979) (Table 1). The number of fungal conks, cavities and damage (i.e., broken top, branch, or both at >10 cm diameter) were recorded (Runde and Capen 1987, Rodewald and Smith 1998) for each tree as well. In considering all secondary cavity-nesting species of interest, the smallest usable tree size listed by Degraaf and Shigo (1985) was a DBH of 10.15 cm (4 in) for black-capped chickadee (*Poecile atricapilla*) nest cavities, so only trees >10 cm DBH were tallied.

With an assistant, I counted all cavity trees by splitting plots into 6 “pie” sections lined by 50-meter tapes and tagging each located tree. Binoculars aided cavity searches. Harrison (1975) provides minimum average nest-cavity dimensions of 6 cm (2 3/8 in) diameter and about 12.7 cm (5 in) deep, with an opening of about 3.5 cm (1 3/8 in) (for black-capped chickadees). Therefore, cavities were counted when estimated to be at least 5 cm diameter by 10 cm deep with an opening >3 cm. The species, DBH, health, height, number of fungal conks, presence of damage, number of cavities, cavity origin (i.e., excavated or non-excavated), and opening size (width and height) were recorded for every cavity tree found within the plot.

Statistical Analyses

To improve normality all percentage data (e.g., slope, overstory cover, understory cover) were arcsine transformed (Zar 1999). Other data were similarly treated using logarithmic transformations when Kolmogorov-Smirnov goodness of fit tests showed normality was thereby improved (Zar 1999). Circular distributions (e.g., plot aspects, cavity openings) were checked for uniformity using the Rayleigh test (Zar 1999).

Analyses of covariance (ANCOVA) were used to find differences in tree cavity abundances among forest cover types for all cavities, and for excavated cavities only. Because cavity abundances may vary accordingly with other plot features (e.g., basal area, tree count, stand age, slope), the suitability of each feature as a concomitant variable in ANCOVA regression models was tested in an additive, stepwise fashion (Dowdy and Wearden 1991). Rayleigh tests showed sufficient evidence to suggest uniform plot distributions for plot aspects in the RS – YB ($P = 0.330$), BC – M ($P = 0.249$), and WO – BO – NRO ($P = 0.336$) forest cover types. Thus, because north-facing stands may have different growth characteristics than south-facing stands, aspect blocks (north and south) were included in the ANCOVA designs.

I used Tukey's test for multiple comparisons to separate means when significant differences among treatments were suggested. I used log-likelihood ratios (i.e., G tests) to find which tree species are more and which species are less likely to contain cavities. All tests were significant at $P < 0.05$. Sequential testing among species allowed for multiple comparisons between species. I did similar tests counting excavated cavities only. To compare heights, diameters, and decay classes of cavity trees to inventory (i.e.,

trees tallied by center point prism methods) conspecifics, I compared mean plot values using paired *t*-tests for each common species using available data.

RESULTS

A total of 912 cavities was found in 707 cavity trees greater than 10 cm DBH. Of the 707 cavity trees, 249 trees contained cavities excavated by woodpeckers. Over 25 tree species were tallied in cavity tree counts and prism counts; about half of these were commonly encountered. The 75 plots were established among 48 forest stands in 16 compartments of the MNF. Forest stands used ranged in area from 2.83 ha to 50.18 ha. The oldest stand age was 188 years, while 78% of stands were 90 - 110 years old. The mean age of RS – YB plots was significantly older than BC – M and WO – BO – NRO plots ($F = 11.45$, $df = 2,72$, $P < 0.0001$) (Table 2). However, no difference in mean basal areas ($F = 0.08$, $df = 2,72$, $P = 0.924$) or stems per plot ($F = 2.86$, $df = 2,72$, $P = 0.064$) were detected among the forest cover types (Table 2).

Red spruce accounted for 50.3% of the mean plot basal area of the 25 RS – YB plots, and yellow birch comprised 24.5% of the mean RS – YB basal area (Figure 2). Also, red spruce and yellow birch accounted for 41.5% and 32.3% of the mean RS – YB stems counts, respectively (Figure 3). Other common tree species on RS – YB plots included American beech, black cherry, eastern hemlock (*Tsuga canadensis*), and red maple (Figures 2, 3). Black cherry was the most commonly tallied tree on BC – M plots (29.1% of mean basal area), followed by sugar maple (23.4% of mean basal area) and red maple (12.4% of mean basal area) (Figures 4, 5). Northern red oak occupied 30.9% of the WO – BO – NRO basal area and 22.1% of the mean stem count per plot (Figures 6,

7). Red maple averaged more stems than northern red oak, but occupied less mean basal area on WO – BO – NRO plots (Figures 6, 7). Chestnut Oak, white oak, black oak, sugar maple, and black locust also were commonly counted in prism tallies (Figures 6, 7).

Cavity Occurrence Among Forest Cover Types

The stepwise procedure selected precipitation, % understory cover, basal area, and inventory stem counts as covariates in the ANCOVA model. When also controlling for plot aspect, ANCOVA results suggest mean cavity tree abundances differed among RS – YB, BC – M, and WO – BO – NRO forest cover types ($F = 5.02$, $df = 2,67$, $P = 0.009$). Tukey's test results show inequality among all forest cover types in mean cavity abundance per plot ($P < 0.05$) (WO – BO – NRO: $\bar{x} = 16.4$, $SE = 5.3$, BC – M: $\bar{x} = 12.7$, $SE = 6.8$, RS – YB: $\bar{x} = 7.2$, $SE = 3.6$). Precipitation, % understory cover, basal area, stem count, and plot aspect together accounted for 53.19% of the variability in cavity abundances among plots.

When counting trees with excavated cavities only, the stepwise procedure selected precipitation, % overstory cover, % understory cover, % shrub cover, basal area, and inventory stem counts as covariates in the ANCOVA model. Again controlling for plot aspect, ANCOVA suggests that mean excavated cavity tree abundances do not differ among RS – YB ($\bar{x} = 3.3$, $SE = 0.46$), BC – M ($\bar{x} = 4.2$, $SE = 0.63$), and WO – BO – NRO ($\bar{x} = 5.1$, $SE = 0.74$) forest cover types ($F = 0.83$, $df = 2,65$, $P = 0.441$). The ANCOVA model accounted for 33.16% of the variability in excavated cavity abundances among plots.

Cavity Occurrence Among Tree Species

More cavities occurred in American beech and sugar maple than other species (15.84% and 15.13% of all cavities, respectively) (Figure 8). Together with yellow birch, red maple, black locust, chestnut oak, and northern red oak, these species accounted for > 75% of all cavities found. American beech, black locust, sugar maple, and yellow birch accounted for > 60% of all excavated cavities. Although red maple was the most common tree among all plots, black locust had the highest proportion of inventory trees with cavities (23.7% of stems had cavities) (Figure 9).

Log-likelihood tests show that black locust, followed by American beech, are significantly more likely to have cavities than stems of all other species (Table 3). Conversely, northern red oak, black cherry, and red spruce were least likely to have cavities. Results were similar when counting excavated cavities only (Table 3).

Cavity Tree Characteristics

When comparing mean diameters of inventory trees to conspecific cavity trees on a by-plot basis, cavity trees were significantly larger than inventory trees (Table 4). In no instance was the mean diameter of inventory trees larger than conspecific cavity trees (Table 4). However, only red spruce showed significant differences in height between inventory trees and cavity trees ($t = 6.18$, $P < 0.0001$) (Table 5). Most (51.79%) American beech cavity trees had broken boles (at > 10 cm diameter), whereas 33.33% of conspecific inventory trees had broken boles. Similarly, 90.48% of the red spruce cavity trees had broken boles, compared to 90.37% of the inventory trees with intact boles.

Cavity trees of all species combined were more decayed than inventory trees in by-plot comparisons ($t = 2.42$, $P = 0.023$). However, most oaks and maples with cavities were not snags, but live trees. Cavity trees in black locust and American beech tended to be snags in various stages of decay. Yellow birch cavity trees varied widely among stages of decay, yet 80.67% of inventory stems were live.

DISCUSSION

Cavity Tree Comparisons Among Forest Types

Differences in cavity abundance among RS – YB, BC – M, and WO – BO – NRO forest cover types were not due to differences in stand ages, basal area, or number of standing stems. The relatively lower cavity tree rate among RS – YB stands was most likely due to the large proportion of live spruce trees within these stands, even though these stands tended to be older. Live conifer trees are known to provide poor nesting and denning opportunities for wildlife (Van Balen et al. 1982). Thus, variations in growth forms of major tree species in each forest cover type also were likely causes for differences in cavity tree abundances. The strong apical dominance and natural pruning characteristics of red spruce will leave only boles (and not branches) as possible cavity sites.

Even with binoculars and no foliage, cavities among hardwoods were difficult to detect. Some portions of large, laterally growing branches couldn't be seen from the ground, so possibly cavities were missed. Healy et al. (1989) estimated that 80% of hardwood cavities were detected by binoculars from the ground in a similar study. However, the differences in growth forms between the red spruce and hardwoods,

coupled with the presence of foliage on the spruce, appeared to balance cavity detectability among the tree species and hence, forest cover types.

Woodpecker excavations did not account for differences in cavity abundances among the forest cover types studied. Among the oak species combined, only 20.5% of all cavities were excavated. Similarly, among black cherry and the maples combined, only 25.6% of all cavities were excavated. However, 76.2% of red spruce cavities and 45.8% of yellow birch cavities were excavated. Clearly, cavities formed by wood decay were predominant among WO – BO – NRO and BC – M forest types, and accounted for differences in cavity abundance among the forest cover types. Additionally, cavities initiated by decay tended to be in the larger diameter trees within plots. Structurally, larger trees of harder wood may be able to better survive injury from damaging agents, such as fire or wind, yet these agents will provide avenues for decay-causing fungi (Oliver and Larson 1996).

Cavity Tree Comparisons Among Tree Species

Carey (1983) found 10.3 cavity trees/ha in 94 to 126 year old maple-beech-birch stands in the Cheat Ranger District of the MNF, slightly lower than the 12.7 cavity trees/ha I found among BC – M plots in the Greenbrier and Potomac Ranger Districts. Beech comprised 36.7% of the cavity trees and only 13.5% of the inventory stems in the BC – M plots I measured. In contrast, Carey (1983) found 29% of the maple-beech-birch cavity trees were American beech, while beech comprised 18% of the inventory point samples.

Almost all beech trees > 10 cm DBH appeared affected by beech bark disease, initiated by the beech scale (Tubbs and Houston 1990). After the beech scale insect attacks the bark, trees become susceptible to canker fungi (*Nectria* sp.) (Tubbs and Houston 1990). A wave of mortality from the disease began on the MNF in the 1990s (Houston 1994); it is likely that when sampling in 1980, Carey (1983) did not find the effects of the disease so widespread. Many of the trees (live and dead) affected by beech bark disease were excavated by woodpeckers and had broken boles. Large broken branches heal relatively slowly, thus many fungi have ample opportunity to penetrate and decay heart wood (Tubbs and Houston 1990).

Large sugar maples are a major part of the cavity tree resource in BC – M stands. Shade tolerant sugar maples and beeches gain growing space through slow-growing, advanced regeneration (Godman et al. 1990). Because growth is slow, it is likely that larger sugar maples are among the oldest trees in forest stands, and some trees may be left from previous cuttings. Left in open growing conditions, sugar maple boles are then subject to epicormic branching (Godman and Brooks 1971), and these side branches may be naturally pruned as competition from faster growing competitors increases. Breakage sites provide spots for fungal attack (Godman et al. 1990). Also, sugar maple terminal buds are subject to forking, especially as trees age (Godman et al. 1990). Breakage increases as forked branches gain mass, thus providing a genesis for cavity formation.

Sugar maple generally outcompetes yellow birch in stands where they coexist (Erdmann 1990). Sugar maple roots may produce an exudate that inhibits root growth of yellow birch, thus providing the maple a growth advantage (Godman et al. 1990). However, most cavities in RS – YB stands are in yellow birch trees. More than 81% of

excavated yellow birch trees (46% of all yellow birch cavity trees) were of advanced decay, and with broken tops. Excavated red spruce cavity trees (71% of all red spruce cavity trees) tended to be in a similar condition. Weak excavating species, such as the red-breasted nuthatch, rely on softer snags for nesting opportunities (DeGraaf and Shigo 1985). Also, it is likely that red squirrels and flying squirrels depend on sounder yellow birch or other northern hardwoods for available cavities.

Like sugar maple, red maple also may tolerate relative shade in the understory for years before becoming released by canopy gaps (Walters and Yawney 1990). However, red maples seldom live longer than 150 years (compared to >300 years for sugar maple), and generally do not attain the diameter growth of sugar maple (Godman et al. 1990, Walters and Yawney 1990). Indeed, red maple inventory and cavity trees had much less diameter growth than other common species of BC – M stands, indicating that most were understory trees. Still, red maple is considered a softer wood than sugar maple, and decay advances much faster in red maple than sugar maple (Walters and Yawney 1990). Nonetheless, red maple displayed a disproportionately low amount of excavated cavities. Most inventory and cavity trees were poor-formed, live trees without broken boles or branches. In all, red maple is probably too limited by diameter growth to be considered an important cavity tree.

Likewise, black cherry apparently does not significantly contribute to tree cavity resources among BC – M stands. A shade intolerant, fast-growing pioneer species, black cherry trees show strong apical and epinastic control (Marquis 1990). Thus, most boles are long, either single or forked, with small crowns unfit for cavity formation. Because black cherry trees are generally dominant in the canopy up to about 80 years, they are

subject to wind and storm breakage (Marquis 1990). However, decay spreads relatively slowly in black cherry, and thus the species is not prone to cavity formation.

Black locust is a shade-intolerant, pioneer species of mixed mesophytic forests, yet single-tree gaps in closed canopies may allow enough growing space for reestablishing black locust trees (Huntley 1990). Whereas sugar maple and beech are shade tolerant, slow-growing northern hardwoods, black locust relies on rapid growth to pioneer forest gaps in central hardwood stands (Huntley 1990). Because of the hardness and durability of black locust wood, it is commonly used for fence posts and railroad ties, for example (Huntley 1990). Also, growing success of black locust decreases with increasing slope, such as along the steep slopes of the MNF (Brown 1962). These qualities combine to make black locust an excellent snag and cavity resource in the MNF. Overtopped trees will not survive, yet black locust snags become a long-lasting, well-used resource for excavating species. Additionally, Sanderson et al. (1975) noted the importance of excavated black locust snags as potential gray squirrel cavity trees in West Virginia. In fact, less than 10% of black locust inventory trees were healthy, and all black locust cavity trees were unhealthy or dead.

Similarly, Carey (1983) found a disproportionate number of black locust with cavities in the Cheat Ranger District of the MNF. However, Carey (1983) found chestnut oak and northern red oak comprised higher percentages of the total cavity tree count than black locust (44%, 19%, and 10%, respectively). In contrast, I found a significantly higher percentage of black locust cavity trees than all other species.

Chestnut oak had the highest cavity tree rate of all oak species, yet cavity tree likelihood was not significantly different from black oak. Chestnut oak has a higher

incidence of decay associated with fire among the steep slopes of the Appalachians than many other oak species, although fire damage to all oaks can allow fungal attacks (McQuilkin 1990). I observed probable fire damage on several plots, which may possibly explain the relatively high cavity tree rate among chestnut oaks. The boles of many central hardwoods that had cavities near the butt also had some evidence of charring. Chestnut oak also was the oak species most likely to be excavated. However, most trees of all oak species appeared undamaged.

A study of gypsy moth damage among several tree species shows highest negative trends in health of northern red oaks and chestnut oaks after defoliation (Showalter 2000). Nevertheless, of the oaks, cavity likelihood was lowest in red oaks, but not significantly lower than in white oak. Although it isn't clear which cavities are caused by gypsy moth defoliation, it does not appear that such damage contributes significantly to the cavity tree resources in the MNF.

Within central hardwood stands of southeast Missouri, black oaks had significantly more cavities than white oaks (Allen and Corn 1990). I found no significant difference in cavity tree likelihood between these 2 species. However, black oak probably occupies less of the basal area in MNF stands than among the forests of Missouri, and possibly basal area isn't large enough to show a difference. Northern red oak occupies much more of the central hardwood forests of the MNF than black oak.

MANAGEMENT IMPLICATIONS

Wildlife Species

Providing adequate resources for cavity-using wildlife among the relict red spruce forest “islands” in the southern Allegheny Mountains will aid in conserving the unique diversity of the region. Red spruce will not provide long lasting snags. The most destructive fungi *Phellinus pini* and *Phaeolus schweinitzii* chiefly occur in already declining and damaged trees, thus accelerating snag loss (Blum 1990). However, the soft snags of red spruce (and yellow birch) will provide nesting opportunities for weak excavating bird species. Red-breasted nuthatches, for example, are limited in breeding to the higher elevations in the southern Allegheny Mountain region (Buckelew and Hall 1994). Similarly, black-capped chickadees prefer mixed deciduous-coniferous and northern hardwoods in West Virginia (Buckelew and Hall 1994).

Yellow-bellied sapsuckers (*Sphyrapicus varius*), decreasing in numbers since the 1920s, also are confined in the region to breeding in middle elevations within the Allegheny Mountains (Hall 1983). Yellow birch can be an important summer food source for sapsuckers, and increased foraging may kill trees (Erdmann 1990). Yellow-bellied sapsuckers also may inflict mortality on red spruce while foraging (Blum 1990). Thus, providing proficient nesting opportunities in other forest types may benefit cavity-nesting species of the RS – YB forest cover types by increasing snag resources.

Virginia northern flying squirrels and red squirrels must rely upon appropriately sized cavities for denning. Both squirrel species rely heavily on red spruce as food sources (Blum 1990, Mitchell 2001). It's not likely that cavities excavated by nuthatches or chickadees provide ample space or adequate protection; squirrels probably rely on

cavities formed by fungal decay. These cavities will occur most often in the larger yellow birch, sugar maple, and American beech that grow either within RS – YB stands or in surrounding northern hardwood forests. Adjacent to or within RS – YB stands, poorly formed sugar maples and beeches should be available as cavity resources for these wildlife species.

Tree Species

Caution should be used when assessing the value of American beech as a cavity tree resource. Beech bark disease was first reported to North America in Nova Scotia in the 1890s, and has spread westward and southward since being introduced (Acciavatti et al. 1993, Houston 1994). Usually, when beech bark disease infects a forest for the first time, a high proportion of large, mature trees are killed (Tubbs and Houston 1990). It is likely that many of the large beech cavity snags presently found in the MNF are a direct result of the beech bark disease. Many of the beech snags were excavated by woodpeckers. Tubbs and Houston (1990) reported high current mortality rates in some southern and western areas of the Adirondack Mountain region. In 1999-2001, the front of high beech mortality was probably beginning at the MNF. After the killing front subsides, stands are replaced with small trees that are inadequate for cavity formation (Houston 1994). Also, mortality is rare in stands in the aftermath of the disease front (Tubbs and Houston 1990).

Carey (1983) suggested that cavity abundance depends on local processes that affect individual trees, such as fire, wind, or storm damage. I found evidence to support his conclusions. Black locust regeneration among mature forest canopies of central

hardwoods depends on canopy gaps. Black locust are poorly formed trees, yet snags have longevity and are major excavating sites for woodpeckers. Similarly, most of the live oaks with cavities were not healthy, well-formed trees. Of the oaks, chestnut oak is a superior cavity tree species.

FUTURE RESEARCH

To protect the relict spruce stands along the Appalachian Mountains, research should continue to focus on explanations for observed increases in spruce mortality rates. Within red spruce stands, home range information of the endangered Virginia northern flying squirrels will aid conservation efforts. Use versus availability information among forest stands with differing amounts of red spruce should be assessed among home ranges of flying squirrels. Such information will be useful in evaluating the potentiality of hardwood cavity trees. Additionally, the relative importance to weak excavating bird species of existing versus excavated cavities in RS – YB stands should be evaluated. Gathering cavity use information will afford better judgment concerning snag resources within the remnant red spruce forest cover types.

To better understand the current situation of American beech as a cavity resource, long-range studies should be considered. It appears that the initial killing front of beech bark disease is now occurring on the MNF. Smaller beech regenerating in the aftermath of the mortality front are not likely to contain suitable cavities. The relative proportions of beech within overstory canopies as well as the relative contributions to cavity tree resources within the MNF should periodically be evaluated to understand the long-term effects of beech bark disease.

Within central hardwood cover types, as well as other forest cover types, the relative suitability of WO – BO – NRO for providing cavity-wildlife cover should be compared to other cover types, such as pure chestnut oak and pure northern red oak. Wildlife use data among cover types will address this issue. Additionally, stands of various ages of the same forest cover type can similarly be assessed.

CHAPTER 3

FACTORS INFLUENCING AVIAN COMMUNITIES AMONG BOREAL, NORTHERN HARDWOOD, AND CENTRAL HARDWOOD FOREST COVER TYPES IN THE SOUTHERN ALLEGHENY MOUNTAINS

Abstract: Insular effects may influence biodiversity among boreal and northern hardwood forest cover types of the southern Allegheny Mountains. These differences may be due to natural characteristics, such as marked topography and an elevational gradient, as well as from past influences, such as poor logging practices. Because of their dependency, cavity-nesting species may be especially vulnerable to changes in forest structure and composition. Analyses among a central hardwood (white oak – black oak – northern red oak), northern hardwood (black cherry – maple), and boreal (red spruce – yellow birch) forest type show no differences in avian species diversity, richness, or overall density, yet avian community composition varied among the 3 forest types. Cavity-nesting species dependent on available tree holes were found most in white oak – black oak – northern red oak plots, which also contained significantly more available cavities than other forest types ($p = 0.009$). Basal area was a consistent covariate among analyses of diversity richness, and density. Besides forest acreage and composition, vertical structure is likely the third major influence on avian community compositions. Future management decisions for biodiversity should consider understory and shrub layers as well as forest overstory composition.

This chapter in the style of *Conservation Biology*.

INTRODUCTION

Habitat fragmentation is considered a main factor in the loss of forest biodiversity (Hagan et al. 1995; Villard et al. 1999; Manolis et al. 2000). Not only have wildlife population declines been attributed to direct losses of suitable habitat, but isolation effects (i.e., habitat configuration) and increased amounts of habitat edges also have negatively affected population levels (Hagan et al. 1995; Villard et al. 1999). Poor timber harvesting practices of the past, such as those throughout the late 1800s in the southern Allegheny Mountains of West Virginia (Clarkson 1993), are often cited as causes of forest fragmentation. Additionally, incipient harvesting and fragmentation affect wildlife population levels quite differently from residual and historical causes (Hagan et al. 1995). Thus, baseline information on wildlife population levels among the various forest cover types is necessary to evaluate effects of current forest management.

Generally, the Allegheny Mountains are considered within the central hardwoods region, yet northern hardwood and boreal forest types also can be found within the immediate area (Eyre, 1980; Hicks 1998). The physiographic Allegheny Mountain section of the Appalachian Plateau runs southwesterly from central Pennsylvania to the highest peaks of West Virginia (Fenneman 1938). At the highest elevations of the Allegheny Mountains in West Virginia, generally above 1000 meters, relict patches of boreal forests remain from cooler, periglacial times (Lesser 1993). Moving down in elevation, forests become a mosaic between higher, north-facing northern hardwood types and lower, south-facing central hardwood stands (Hicks 1998).

Past management influences on forests also are usually manifested in present forest stands. In West Virginia, for example, valley forests were cleared to establish farmsteads, and red spruce tracts at higher elevations were girdled and burned to produce cattle pastures and later logged for timber (Clarkson 1993; Stephenson and Adams 1993). Removal of the timber has left mostly a mosaic of 2nd and 3rd-growth forests (Stephenson 1993). Preferential harvesting and introduced diseases and pests also have changed stand composition over time (Carvell 1986; Acciavatti et al. 1993). These past effects, as well as others, influence the continuity of apparently contiguous wildlife habitats.

Furthermore, since the 1960s, evidence shows that boreal forests of North America are puzzlingly shrinking in area, mainly due to increasing mortality rates of red spruce (*Picea rubens*) and balsam fir (*Abies balsamea*) at higher elevations (Stephenson and Adams 1993). Not only are numerous bird species of the Allegheny Mountains limited in breeding to the boreal forests (Hall 1983), but the entire populations of the federally endangered Virginia northern flying squirrel (*Glaucomys sabrinus fuscus*) and Cheat Mountain salamander (*Plethodon nettingi*) are within these relict spruce forest patches (Green and Pauley 1987; Odom et al. 2001).

Island biogeography presumes that the number of species inhabiting an island is inversely proportional to the distance of the island from the mainland (MacArthur and Wilson 1967, Davidar et al. 2001). This premise also may hold true concerning the number of avian species breeding in the boreal and northern hardwood forest cover types of the southern Allegheny Mountains region (Hall 1983). For examples, the boreal spruce and northern hardwood forest patches of West Virginia provide breeding 'islands'

to many bird species, including the yellow-bellied sapsucker (*Sphyrapicus auratus*), red-breasted nuthatch (*Sitta canadensis*), black-capped chickadee (*Poecile atricapilla*), and black-throated blue warbler (*Dendroica caerulescens*) (Hall 1983). Furthermore, these northern forest cover patches are non-contiguous and at the southern limit of breeding ranges for numerous bird species, including the alder flycatcher (*Empidonax alnorum*), Swainson's thrush (*Catharus ustulatus*), hermit thrush (*Catharus guttatus*), magnolia warbler (*D. magnolia*), northern waterthrush (*Seiurus noveboracensis*), and purple finch (*Carpodacus purpureus*) (Hall 1983). Thus, isolation effects similar to those incurred from forest fragmentation effects are induced upon breeding birds of northern forest cover within the southern Allegheny Mountains region.

Although habitat requirements differ for each wildlife species, diversity and abundances of some species guilds, such as cavity-using wildlife, are suitable indicators of forest health trends (Carey 1983). Primary users (e.g., woodpeckers) excavate their own cavities, and true secondary cavity-using species rely on available holes for nesting (Martin and Eadie 1999). Weak excavators (e.g., red-breasted nuthatch, black-capped chickadee) use cavities made by primary excavators, yet also excavate nest sites if soft wood is available (Martin and Eadie 1999).

Furthermore, concerns about possible negative impacts of forest histories on cavity-tree resources have led to numerous publications relating cavity tree abundances to forest characteristics (i.e., cover types, stand features) and at times management practices (Newton 1994). Effects of fragmentation are readily apparent in many of these and other studies as well. For example, although recently clearcut areas in the Jefferson National Forest of southwest Virginia attracted downy (*Picoides pubescens*) and hairy

woodpeckers (*Picoides villosus*), 12-year-old stands remained virtually unused by these woodpeckers (Conner and Crawford 1974). Also, on timber stand improvement forest plots of central Pennsylvania, Stribling et al. (1990) found bird community richness and abundance significantly higher on plots with snags retained than on control plots. Similarly, even-aged plots with reserve trees in central Pennsylvania were used more often than traditional clearcut stands by several interior forest-associated bird species (Rodewald and Yahner 2000).

The Monongahela National Forest (MNF) of West Virginia was formed to protect the forest resources in the southern Allegheny Mountains (Clarkson 1993), thus providing an excellent resource for monitoring wildlife population trends. My objectives were to: 1) compare breeding bird diversity, richness, and density among central hardwood, northern hardwood, and boreal forest cover, 2) analyze avian community compositions among the 3 forest categories, 3) compare cavity-using bird diversity, richness, and density among the 3 forest categories, 4) analyze relationships between secondary-cavity using birds (i.e., birds dependent on available cavities) and tree cavities among the 3 forest categories, and 5) develop management recommendations for the MNF. For purposes here, weak excavating species are included in the secondary cavity-using guild.

STUDY AREA

The study was conducted on the Potomac and Greenbrier Ranger Districts of the MNF, in Pendleton, Pocahontas, and Randolph Counties, West Virginia. More than 80 % of

Randolph and Pocahontas Counties are forested, whereas wider valleys in Pendleton County account for slightly more farmland and less forest (Buckelew and Hall 1994). Plots were divided evenly among 3 Society of American Foresters cover types in the southern Allegheny Mountains: white oak – black oak (*Q. velutina*) – northern red oak (*Q. rubra*) (WO – BO – NRO), which includes the sub-type scarlet oak (*Q. coccinea*) – chestnut oak; black cherry – maple (BC - M); and red spruce – yellow birch (RS - YB)(Eyre 1980). These types represent central hardwood, northern hardwood, and boreal forests, respectively.

All study plots were within 27 km (16.8 mi) of a geographic center near Lost Run in Highland County, Virginia, which is about 11.8 km (7.3 mi) east of the Greenbrier District Ranger Station in Bartow, West Virginia. Elevation ranged from about 540 m (1772 ft) to 1481 m (4861 ft). However, relief usually ranges between 300 m (1000 ft) and 500 m (1600 ft) (Hall 1983). The terrain is hill-and-valley with some slopes near 70 % grade (Pyle 1982).

Prevailing winds come from the west, creating the greatest amounts of precipitation along the upper-west slopes and a rain-shadow effect along east slopes (Buckelew and Hall 1994). Annual precipitation ranges from 94 – 132 cm/yr (Buckelew and Hall 1994). Average temperatures along the southern Allegheny Mountain ridgeline are –8°C (18°F) in winter, and 19°C (66°F) in summer with a maximum of 24°C (76°F) (Estepp 1992). Study plots were located on 10 soil associations (Pyle 1982; Estepp 1992; Flegel 1999). Site indices typically range from 35 to 80, indicating the expected height of trees after 50 years growth (Pyle 1982; Estepp 1992; Flegel 1999).

METHODS

Forest Cover Types

To analyze bird quantities among central hardwoods, northern hardwoods, and boreal forests of the southern Allegheny Mountains, I chose to focus on 1 SAF forest cover type in each general forest category so variations in stand compositions among categories could be minimized. I also used an arbitrary minimum stand age of 90 years so that only mature stands would be compared, yet a practical amount of usable stands would exist. I chose the white oak – black oak – northern red oak type (*Quercus alba* – *Q. velutina* – *Q. rubra*) as a central hardwood because each of these species is commercially important, most other central hardwood species are common associates. I also focused on black cherry – maple (*Prunus serotina* – *Acer* spp.) stands among northern hardwoods because of the current importance of black cherry veneer in timber markets. To reduce possible bias resulting from different species growth forms, I chose to focus on red spruce – yellow birch (*Betula alleghaniensis*) rather than pure red spruce as a boreal forest cover type.

Plot Establishment

I randomly selected appropriate forest stands from a list of stands ≥ 90 years in which to establish study plots. I avoided areas with recent or intense management activity, and areas more than 1200 m from a drivable road. Using compartment maps from the Forest

Service, I selected a random distance and compass bearing from an access point to establish the center for each 50-m radius plot. Each plot was within 1 mapped stand, and plots were at least 250 m apart for independent sampling (Ralph et al. 1995). I set up 30 plots in each SAF cover type for a total of 90 plots. On 75 plots (25 in each forest type) I counted cavity trees. All plots were established when leaves were absent from trees to facilitate cavity searching.

Plot Inventory and Cavity Search

Center point slope and prevailing aspect were recorded (Marcot 1983; Marzluff and Lyon 1983). I determined plot elevations from a geographic information systems (GIS) analysis. More specifically, I placed center point location information on a digital elevation grid (with cell sizes of 90 m) of West Virginia using ArcView GIS software. Elevation values were downloaded from the West Virginia Natural Resources Analysis Center website (www.nrac.wvu.edu, December 12, 2001).

In summer months I estimated percent overstory cover (codominant and dominant canopy), understory cover (<2 m tall to overtopped canopy), and shrub cover (<2 m tall) at center points and estimates at 3 random equidistant points about 25 m from the plot center. Similar to the method developed by James and Shugart (1970), I estimated overstory, understory and shrub layer the percent of total cover of each vegetation layer in 10 m radius circles at each of the four points within the plot. I then averaged these readings for an overall plot estimation.

I sampled center points via a prism with a basal-area factor of 10 to determine basal area and tree tallies within plots. For each tallied tree the species, diameter at 1.5 m (DBH), and height (determined with a clinometer) were recorded. Plot composition, basal area, and number of standing trees were estimated from prism-tally information (Avery and Burkhart 1997). In considering all secondary cavity-nesting species of interest, the smallest usable tree size listed by Degraaf and Shigo (1985) is a DBH of 10.15 cm (4 in) for black-capped chickadee nest cavities, so only trees > 10 cm DBH were tallied.

With an assistant and binoculars, I counted all cavity trees by splitting plots into 6 “pie” sections lined by 50-m tapes and tagging each located tree. Harrison (1975) provides minimum average nest-cavity dimensions of 6 cm (2 3/8 in) diameter and about 12.7 cm (5 in) deep, with an opening of about 3.5 cm (1 3/8 in) (for black-capped chickadees). Therefore, cavities were counted when estimated to be at least 5 cm diameter by 10 cm deep with an opening >3 cm.

Breeding Bird Counts

I estimated bird quantities using a 50-m fixed radius point count method on all plots (Ralph et al. 1995). Thirty original plots (10 per forest type) were established and visited twice between 27 May and 2 July 2000, while all plots were twice counted between 26 May and 4 July 2001. Counts were 10 minutes and duration, and all sky and wind conditions were acceptable as per Ralph et al. (1995). Because squirrel populations also use tree cavity resources (Sanderson 1975; DeGraaf and Shigo 1985), red squirrels

(*Tamiasciurus hudsonicus*), eastern gray squirrels (*Sciurus carolinensis*), and eastern chipmunks (*Tamias striatus*) also were tallied during bird counts. Plot information was pooled between visits but separated by year. For comparisons among forest types, all maximum yearly plot tallies were used in statistical analyses.

Statistical Analyses

Analyses focused on determining differences in species richness, densities, and diversity among the 3 forest cover types. Because within-year counts were not mutually independent, I calculated yearly richness and density for each plot by using the maximum species abundance values between the 2 yearly point counts (Nur et al. 1999). I used Shannon's Index to quantify yearly plot diversities (Nur et al. 1999). I similarly calculated species richness, plot density, and diversity values for totals of all cavity species, and secondary-using cavity species only.

Because of unequal plot sample sizes between years, data were analyzed by 2 principle methods to include information from all points in both years. First, between year data was tested using a nested analysis of variance (ANOVA) design; forest types were treatment groups, with 10 plots per treatment, and 2 replications per plot (Dowdy and Wearden 1991). Diversity, richness, and density were tested using the nested design for all counted species, then all cavity species, and lastly only secondary species.

Secondly, all 90 plots in 2001 were tested using an analysis of covariance (ANCOVA) (Dowdy and Wearden 1991). Because species diversity, richness, and densities may vary accordingly with other plot features (e.g., basal area, tree count, stand

area), the suitability of each feature as a concomitant variable in ANCOVA regression models was tested in an additive, stepwise fashion (Dowdy and Wearden 1991). I fitted separate regression models in ANCOVAs for species diversity, richness, and plot densities for all counted wildlife species. I repeated the processes using only cavity-using species, and then only secondary-using species, to determine the dependent variable values for each plot.

I tested the equality of occurrence for guilds and species among the 3 forest types in 3x2 χ^2 contingency tests (Dowdy and Wearden 1991; Zar 1999). Only species with expected frequencies (i.e., total number of observed frequencies/3 for each forest type) of >5 individuals/forest type were tested (Dowdy and Wearden 1991; Zar 1999). I used logistic regression models to determine if individual species presence on plots was significantly related to plot characteristics which included: basal area, stem density, overstory cover, understory cover, shrub cover, elevation, and basal areas and stem densities of the 8 most common tree species (Nur 1999). I used Hosmer and Lemeshow goodness-of-fit tests to measure model significance (Cody and Smith 1997).

Because only 75 plots (25 per forest type) were searched for cavities, cavity tree counts per plot were not used in ANCOVAs or logistic regressions. Instead, I tested the suitability of cavity tree counts as covariates for cavity-using wildlife values in additional regression models. I fitted regression models for the 75 plots as I did for all 90 plots – in an additive, stepwise fashion. I tested density values independently for each of the various guilds of cavity-using wildlife, disregarding forest cover types. I tested for significant relationships between individual cavity-using species and cavity tree

abundances using logistic regressions (Nur 1999). As with wildlife species data, I used an ANCOVA to determine if cavity tree abundances differed among forest cover types.

To improve normality all percentage data (e.g., slope, overstory cover, understory cover) were arcsine transformed (Zar 1999). Other data were similarly treated using logarithmic transformations when Kolmogorov-Smirnov goodness of fit tests showed normality was thereby improved (Zar 1999). Richness and density values for cavity-using wildlife guilds were analyzed using a square-root transformation (Zar 1999). I used Tukey's test for multiple comparisons to separate means when significant differences among treatments were suggested (Dowdy and Wearden 1991; Zar 1999). All tests were significant if $P < 0.05$.

RESULTS

A total of 60 wildlife species was tallied among the 3 forest cover types. Thirty-nine species were found in RS – YB plots, whereas 45 and 42 species were counted in BC – M and WO – BO – NRO plots, respectively. The 2001 maximum tally of all species on all plots totaled 1154 animals; 443 were counted in RS – YB stands, 376 individuals in BC – M stands, and 335 individuals in WO – BO – NRO stands. Using the maximum species abundance values between years for each plot, the maximum densities were 11.6 animals/ha/year in RS – YB plots, 9.8 animals/ha/year in BC – M stands, and 8.8 animals/ha/year in WO – BO – NRO plots for all plots within types combined.

Twenty-eight species were recorded at least 15 times using maximum tallies at each plot for each species (Table 1). Only 6 of the 28 species showed equal occurrences

among all forest cover types (Table 1). The most numerous species among all plots per breeding season were the red-eyed vireo (*Vireo olivaceus*) and black-throated green warbler (*Dendroica virens*), each recorded 60 times in 2001 (Fig. 1). Only the dark-eyed junco (*Junco hyemalis*) was found on all RS – YB plots. The red-eyed vireo was most widespread among BC – M and WO – BO – NRO plots, occupying 28 and 24 of 30 plots, respectively. In contrast, the red-eyed vireo occupied only 10 RS – YB plots.

Logistic regression models explained the likelihood of occurrence of 13 bird species (Appendix VII). Both elevation and shrub cover (%) varied positively with the presence of 3 species and varied negatively with the presence of 2 species. Among tree species, increased basal area per plot of yellow birch and sugar maple together increased the likelihood of occurrence of the Blackburnian warbler (*Dendroica fusca*), black-throated blue warbler, and winter wren (*Troglodytes troglodytes*). Separately, yellow birch stem densities increased with the increased likelihood of 4 species, while sugar maple stem densities increased with the increased likelihood of 3 species.

Yearly maximum counts of cavity-using wildlife species for 2001 alone were equal among forest types; 117 were observed in RS – YB plots, 118 were observed in BC – M plots, and 116 were spotted in WO – BO – NRO plots ($\chi^2 = 0.017$, $df = 2$, $p = 0.992$). Secondary cavity using species accounted for 304 of the 351 total cavity-using species observed; 105 were seen in RS – YB plots, 98 were seen in BC – M plots, and 91 were seen in WO – BO – NRO plots ($\chi^2 = 1.00$, $df = 2$, $p = 0.607$). Considering all cavity-using species among all plots, red squirrels were most frequently tallied (0.43/ha/year), followed by eastern chipmunks (0.36/ha/year) (Fig. 1). Of bird species,

black-capped chickadees were most frequently counted (0.33/ha/year) among all plots (Fig. 1).

Fourteen wildlife species that show at least facultative use of tree cavities as nesting or denning sites were observed during point counts (Appendices VIII, IX). Ten cavity-using species were found within RS – YB plots, all 14 species were found within BC – M plots, and all but the winter wren were found within WO – BO – NRO plots. However, only 1 red squirrel and 1 red-breasted nuthatch were seen in WO – BO – NRO plots. Of the 14 species observed, 5 species were primary cavity-using species, and 2 species were weak excavators.

Analyses of All Species Combined

Between-year analyses of species diversity was similar among RS – YB, BC – M, and WO – BO – NRO forest types ($F = 1.95$, $df = 2,27$, $p = 0.162$) (Table 2). Likewise, overall species richness was similar among the 3 forest cover types when considering both years data ($F = 1.70$, $df = 2,27$, $p = 0.202$). Furthermore, total species densities among the 3 forest cover types were not significantly different ($F = 2.53$, $df = 2,27$, $p = 0.099$).

Considering all data from 2001, percent shrub cover ($r^2 = 0.025$) and basal area of standing wood ($r^2 = 0.045$) together explained 7.00% of variations in species diversity within each forest cover type. The all species diversity ANCOVA for 2001 data suggested species diversities were not significantly different among the 3 forest cover types ($F = 2.94$, $df = 2,85$, $p = 0.059$) (Table 2).

The percent shrub layer ($r^2 = 0.029$), basal area ($r^2 = 0.041$), and number of inventory trees ($r^2 = 0.029$) together explained 9.91% of the variation in species richness within each forest cover type. There was sufficient evidence that species richness was higher among RS – YB plots than WO – BO – NRO plots, while BC – M plot richness did not significantly differ from the other forest cover types in species richness (Table 2).

The percent shrub layer ($r^2 = 0.043$), basal area ($r^2 = 0.032$), and number of inventory trees ($r^2 = 0.041$) together explained 11.66% of the variation in wildlife densities within each forest cover type. The mean plot density in RS – YB stands of all species combined was significantly higher than on BC – M and WO – BO – NRO stands (Table 2).

Analyses of Cavity-nesting Wildlife Species

The between-year mean diversity of all cavity-using species did not differ significantly among WO – BO – NRO, BC – M, and RS – YB plots ($F = 0.76$, $df = 2,27$, $p = 0.476$) (Table 2). Similarly, mean species richness of all cavity-using species did not significantly differ among the 3 forest cover types ($F = 0.59$, $df = 2,27$, $p = 0.536$) (Table 2). Likewise, mean plot densities of all cavity-using animals did not differ among the 3 forest cover types ($F = 1.05$, $df = 2,27$, $p = 0.363$) (Table 2).

For secondary cavity-using species only, species diversity was not significantly different among the 3 forest cover types ($F = 0.33$, $df = 2,27$, $p = 0.725$) (Table 2). Similarly, secondary cavity-using species richness did not differ among the 3 forest cover types ($F = 0.14$, $df = 2,27$, $p = 0.873$) (Table 2). Also, secondary cavity-using animal

densities were not significantly different among the 3 forest cover types ($F = 0.46$ df = 2,27, $p = 0.636$) (Table 2).

Considering data from 2001 only, basal area of standing wood varied significantly with all cavity-using species diversity ($r^2 = 0.048$), richness ($r^2 = 0.049$), and wildlife densities ($r^2 = 0.048$) among all plots. The all cavity-using species diversity ANCOVA for 2001 data suggested species diversities were similar among the 3 forest cover types ($F = 0.01$, df = 2,86, $p = 0.987$) (Table 3). All cavity-using species richness also was similar among the 3 forest cover types ($F = 0.02$, df = 2,86, $p = 0.976$) (Table 3). Likewise, cavity-using animal densities were similar among the 3 forest cover types ($F = 0.16$, df = 2,86, $p = 0.854$).

Considering the secondary cavity-using species guild, basal area of standing wood ($r^2 = 0.067$) and percent overstory cover ($r^2 = 0.023$) varied significantly with secondary cavity-using species diversity among all plots ($r^2 = 0.090$). The secondary cavity-using species diversities were similar among the 3 forest cover types ($F = 0.74$, df = 2,85, $p = 0.479$) (Table 3). Similarly, basal area ($r^2 = 0.049$) and percent overstory cover ($r^2 = 0.024$) varied significantly with secondary cavity-using species richness among all plots ($r^2 = 0.113$). All cavity-using species richness did not differ significantly among the 3 forest cover types ($F = 1.11$, df = 2,85, $p = 0.334$) (Table 3). Basal area was the lone significant covariate with secondary cavity-using animal densities among 2001 plots ($r^2 = 0.069$). Secondary cavity-using animal densities were similar among the 3 forest cover types ($F = 0.83$, df = 2,86, $p = 0.441$).

Relationships of Cavity-using Wildlife to Cavity Tree Abundances

Mean cavity tree abundances differed among RS – YB, BC – M, and WO – BO – NRO forest cover types ($F = 5.02$, $df = 2,67$, $p = 0.009$). Yet, there is insufficient evidence to suggest that a significant relationship exists between the number of cavity trees per plot and all cavity-using species densities per plot ($F = 0.95$, $df = 1,73$, $p = 0.332$, partial $R^2 = 0.013$). Similarly, no significant relationship was found between the number of cavity trees per plot and secondary cavity-user densities ($F = 0.29$, $df = 1,73$, $p = 0.590$, partial $R^2 = 0.004$). However, after removing weak excavating species from the secondary cavity-using guild, a significant relationship was found between cavity trees per plot and true secondary cavity-using animal densities ($F = 8.94$, $df = 1,73$, $p = 0.004$, partial $R^2 = 0.109$). Logistic regression analyses showed no significant relationships between the likelihood of each individual cavity-using species presence and the abundance of cavity trees.

DISCUSSION

Forests of the southern Allegheny Mountains are a mosaic of hardwood, northern hardwood, boreal forest cover types (Buckelew and Hall 1994; Hicks 1998). Because of the differences in silvicultural composition, I hypothesized that wildlife species diversity, richness, and densities would differ among these forest classes as well. Additionally, I hypothesized that cavity-using wildlife in particular would differ in diversity, richness and density among the 3 forest classes because cavity tree densities are not equal among

these forest classes. Cavity nesting birds, for example, may be useful as forest health indicators because of their rigid link to standing trees, particularly secondary-using species dependent on available holes for nesting (Carey 1983). Using RS – YB, BC – M, and WO – BO – NRO forest cover types to represent the 3 forest classes, I found no evidence to support the hypotheses that all species diversity, richness, and density, as well as all cavity-using species diversity, richness, and density, differ among the forest cover types. Thus, it appears that the ability to support avian and cavity-using communities is relatively equal among mature forest stands (i.e., >90 yrs) of the 3 main forest classes within southern Allegheny Mountain forests, yet the likelihood of occurrence of individual species varies with individual stand characteristics.

Of habitat structure, the basal area of standing wood was the only consistent covariate in wildlife guild diversity, richness, and density models. In central Allegheny Mountain hardwood forests bird species richness and abundance sharply increased in stands with basal areas below 18 m²/ha (but not for interior forest species), and decreased sharply in stands with basal areas exceeding 26 m²/ha (due to diminishing edge species) (Ross et al. 2001). The mean basal area of my study plots was 26-27 m²/ha and mean stand age was about 103 yr (Chapter 2). Higher basal areas are generally associated with lower shrub and understory density. In turn, greater vertical diversity (i.e., higher shrub and understory densities) may accommodate greater avian diversity and abundances (Rodewald and Smith 1998; Hobson and Bayne 2000). Thus, management strategies involving timber harvesting at 90 – 100 yr rotations should mimic small gap disturbances within forest patches to optimize bird diversity and richness among forest edge and interior species.

Wildlife Species Among Forest Cover Types

Point count surveys did not detect differences in wildlife species diversity or richness among RS – YB, BC – M, and WO – BO – NRO forest cover types, yet avian community structures within southern Allegheny Mountain forests vary along an elevational gradient. Some species were only recorded in RS – YB stands, such as Swainson's thrush and the red crossbill (*Loxia curvirostra*). Other species, such as the winter wren and hermit thrush, were only counted within the northern forest types. Three species were found only in BC – M stands, yet only the alder flycatcher was recorded more than once. Lower down, the white-breasted nuthatch (*Sitta carolinensis*), tufted titmouse (*Baeolophus bicolor*), and wood thrush appeared only in hardwood stands, while the eastern wood-pewee (*Contopus virens*) and black-and-white warbler (*Mniotilta varia*) were observed only in WO – BO – NRO plots.

Differences in forest structure, such as basal area, understory and shrub cover, among stands of the same forest type may shape differences in breeding bird community structure. Chances of black-throated green warbler presence seemed to increase with increased stand basal area and decreased stem densities and the Blackburnian warbler also was associated with larger diameter trees. Likewise, Hobson and Bayne (2000) found these species more abundant on contiguous forest tracts than on fragmented areas. Openings in understory and shrub cover negatively impact black-throated blue warbler forest movements (Belisle et al. 2001, Harris and Reed 2001), thus I found black-throated blue warbler presence associated with denser shrub layers. Moreover, I found the Canada warbler (*Wilsonia canadensis*) only in RS – YB and BC - M plots with shrub cover

>75%, with rhododendron (*Rhododendron maximum*) the major shrub component.

Hobson and Schiek (1999) found significantly more Canada warblers in 28 year-old post-harvest stands than on uncut stands, possibly due to the denser shrub layer on post-harvest stands.

I found blue-headed vireo (*Vireo solitarius*) presence associated with understory cover, in concurrence with results from a Canadian boreal forest (Drolet et al. 1999). In contrast, Drolet et al. (1999) found the American robin (*Turdus migratorius*) in association with poorly forested landscapes. Similarly, I found the American robin in association with increased stems counts of black cherry, an early successional species (Marquis 1990), and red maple, which is common on poor growing sites (Walters and Yawney 1990).

Furthermore, the wood thrush (*Hylocichla mustelina*), Swainson's thrush, hermit thrush, and veery (*Catharus fuscescens*) are all considered ground-foraging species, yet foraging heights of the thrush species were stratified among species present from 0 – 8 m above ground level (Holmes and Robinson 1988). Wood thrushes spend >98 % of foraging time in < 2 m from the ground (Holmes and Robinson 1988). Similarly, I found the likelihood of wood thrush presence increased significantly with increased overstory cover, which suggests less understory and shrub cover presence. Furthermore, Swainson's thrushes will use a slightly higher foraging substrate (Holmes and Robinson 1988). Likewise, I found the likelihood of Swainson's thrush presence increased significantly with increased shrub cover. Thus, the presence or absence of a particular bird species may not wholly depend on forest cover type; the amount and quality of sub-canopy vegetation also may influence avian community structure.

The occurrences of 9 of 13 species were directly related to amounts of sugar maple and yellow birch present in stands. These tree species occur together in greatest proportion in an elevational gradient between the pure red spruce stands and northern hardwood forest types such as BC – M, maple – beech (*Fagus grandifolia*) – birch, and beech – sugar maple (Eyre 1980). Thus, edge effects (i.e., increased species occurrences) may happen between forest cover types of similar ages.

As with foraging substrate resources, I found evidence that cavity tree resources may influence dependent, secondary cavity-nesting bird densities. Conifers usually will not hold durable and usable cavities for secondary species (Van Balen et al. 1982). Indeed, I observed the tufted titmouse and white-breasted nuthatch only among hardwood stands. More so, cavity tree abundances were highest within the WO – BO – NRO forest cover type, along with 75% and 66% of all tufted titmouse and white-breasted nuthatch observations, respectively. In contrast, I observed weak-excavating species (i.e., red-breasted nuthatch, black-capped chickadee) mostly in the RS – YB forest cover type (85% and 63% of all observations, respectively), and tree hardness influences nest-site choices of excavating birds (Schepps et al. 1999). Thus, the softer, decayed wood of red spruce and yellow birch may provide easier excavating substrate than other hardwood species for weak excavators. Furthermore, territoriality has been shown to influence differential habitat use among sympatric chickadees (Hill and Lein 1989). The larger tufted titmouse and white-breasted nuthatch may out-compete the smaller red-breasted nuthatch and black-capped chickadee for territories, thus the weak-excavators are relegated to exploiting that part of their niche where there is no sympatric overlap.

Nest parasitism by the brown-headed cowbird (*Molothrus ater*) (hereafter referred to as cowbird) has been identified as a limiting factor to nest success of several interior forest bird populations (Burke and Nol 2000; Flaspohler and Temple 2001). The cowbird is associated with open fields and pastures, yet may penetrate >300 m into forested landscape to find other active nests in which to lay eggs (Flaspohler and Temple 2001). I noted cowbirds only in hardwood plots (i.e., BC – M and WO – BO – NRO cover types). The WO – BO – NRO plots especially are closer to valley farmlands, thus chances of cowbird nest parasitism would be greatest among these forests due to elevational aspects. Even gypsy moth defoliation of large oaks (>38.1 cm diameter) may provide adequate openings for cowbird penetration within otherwise contiguous tracts of forested cover (Bell and Whitmore 2000). In West Virginia, Bell and Whitmore (2000) found greatest nest success of Acadian flycatchers (*Empidonax virescens*) in forests with low snag abundance and hence, increased canopy cover. Similarly, I found Acadian flycatcher presence associated with overstory cover. Thus, some forested land may be non-productive as breeding habitat. Such ideas have led others to conclude that permanent forest loss (e.g., from development, road construction) may be more detrimental to forest health than managed logging practices (Fredericksen 1998).

In contrast, red squirrels and eastern chipmunks (i.e., sciurids), which may compete for tree holes with secondary cavity-nesting birds, may be major nest predators to open nesting bird species (King et al. 1998). Both sciurids may be associated with interior forest conifer cover (King et al. 1998). Indeed, I found most red squirrels in plots with >10% cover of red spruce; others were noted in association with eastern hemlock.

Similarly, I found many eastern chipmunks in association with eastern hemlock among hardwood cover.

Management Implications

Analyzing spruce forests across northern North America, Nekola and White (1999) found that similarities in vegetative diversity decreased with increased distance between forest patches. Thus, wildlife species associated with vegetative cover also will decline with increased separation from similar cover. Furthermore, variations in population trends of many Neotropical migrant birds appear correlated with elevation (James et al. 1996). To maintain biodiversity among southern Allegheny Mountain boreal forests, continuity among cover at varying elevations is a main priority. Although past abuses of southern Allegheny Mountain forests have prompted increased scrutiny of timber harvesting practices, relatively little attention is given to expanding development and obligatory road construction (Fredericksen 1998). Nonetheless, these advances produce more permanent scars among otherwise contiguous forest tracts.

In the southern Allegheny Mountains, if development were minimized among the higher northern hardwood and boreal forests, negatively impacting edge effects also would be minimized on boreal forests. Still, because red spruce stands are shrinking in area, greater amounts of yellow birch and sugar maple will grow in place of the spruce. Because the chances of occurrence of many bird species increase with increasing sugar maple and yellow birch, managers should expect to see positive trends in populations of

many species. However, some species populations, such as the red-breasted nuthatch and winter wren will likely experience negative impacts.

Other edge effects (i.e., cowbird parasitism) presently are more apparent among the lower, central hardwood forest stands. In the MNF of West Virginia, Duguay et al. (2001) found nest parasitism rates by cowbirds on 4 of 5 host species relatively equal among clearcut, two-aged, and control stands 15 years after harvesting. Therefore, the most important factors to consider when harvesting may be landscape level arrangements of silvicultural treatments, as well as treatment acreage, rather than the actual treatments themselves.

Point count results indicate that breeding bird communities may differ among forest cover types. Presence of some bird species, for example the red-breasted nuthatch, appears related to the compositional structure of forest cover. Presence of other species, for example Swainson's thrush, appears directly related to vertical structure. In turn, vertical structure also may depend on the compositional structure of overstory tree species. Moreover, abiotic edge effects, such as increased wind strength, have been shown to influence the amount of vertical foraging substrate used by tufted titmice and Carolina chickadees (*P. carolinensis*), as well as on a horizontal plane (Dolby and Grubb 1999).

My results concur with Hobson and Bayne (2000), for example, who found increased conifer in Canadian mixed wood stands influenced use by bird species such as the magnolia warbler (*Dendroica magnolia*). Similarly, increased density of shrub cover in mature stands resulted in greater abundances of Canada warblers (Hobson and Bayne

2000). Thus, when considering wildlife needs, forest managers should not only regard stand composition and size, but vegetative structure as well.

Generally, on a landscape level avian species reproductive output is highest with minimal cover fragmentation and lowest with maximum cover fragmentation (With and King 2001). However, density of a wildlife species is not necessarily a good indicator of habitat quality, if habitat quality is to be measured by reproductive success (Vickery et al. 1992; Roberts and Norment 1999). For example, although breeding male abundances may not differ among forest stands, pairing success of breeding males may correlate with variations in habitat characteristics such as forest stand composition and structure (Roberts and Norment 1999). Furthermore, nest success may vary between breeding pairs in apparently (i.e., compositionally and structurally) similar forest stands due to conditions such as differential cowbird parasitism (Donovan et al. 1995).

Future Considerations

Reproductive output may be a better indicator of habitat suitability than species density (Hagan et al. 1996). Thus, nest searches and monitoring should be done to provide better habitat suitability information. Fledgling success rates should be compared among forest stands for better suitability information.

When making decisions concerning biodiversity issues managers should not think of forest stands only as a 2-dimensional layout. Vertical structure can be just as important as stand size, composition, and juxtaposition across a horizontal landscape. Perhaps the best tool for making such determinations is GIS software. Field information

should include information about the vertical structure of forest cover. Analysis with GIS allows the overlaying of various layers of data coverage, so stand information can include not only information about overstory composition, but also information about understory and shrub layer vegetation. For avian diversity, understory and shrub composition may be just as important as overstory cover. Notwithstanding, GIS analysis allows spatial considerations across the horizontal plane as well. Therefore, the effects on biodiversity of the juxtaposition of various silvicultural treatments across a landscape also may be assessed. For example, point count information should be collected from RS – YB, BC – M, or WO – BO – NRO stands of various ages. Over time, the 3-dimensional changes in point vegetation characteristics can be monitored and tested along with information regarding wildlife species richness and densities. Such analyses would likely provide more useful and complete information than constantly testing and making inferences from only certain aspects of the complete picture. Also, it is probably less labor-intensive.

red-tailed hawk	<i>Buteo jamaicensis</i>	1	0	0
rose-breasted grosbeak	<i>Pheucticus ludovicianus</i>	0	2	0
ruby-throated hummingbird	<i>Archilocus colubris</i>	0	0	1
scarlet tanager	<i>Piranga olivacea</i>	1	3	3

Appendix VIII Continued.

Common Name	Scientific Name	Forest Type ^a		
		S	N	C
Swainson's thrush	<i>Catharus ustulatus</i>	4	0	0
tufted titmouse ^b	<i>Baeolophus bicolor</i>	0	1	3
veery	<i>Catharus fuscescens</i>	3	1	4
white-breasted nuthatch ^b	<i>Sitta carolinensis</i>	0	2	2
winter wren ^b	<i>Troglodytes troglodytes</i>	3	1	0
wood thrush	<i>Hylocichla mustelina</i>	0	5	4
yellow-bellied flycatcher	<i>Empidonax flaviventris</i>	0	1	0
yellow-bellied sapsucker ^b	<i>Sphyrapicus varius</i>	0	2	5
yellow-rumped warbler	<i>Dendroica coronata</i>	2	0	0

^aForest types are as follows:

S - subalpine (red spruce - yellow birch) forest cover type;

N - northern hardwood (black cherry - maple) forest cover type; and

C - central hardwood (white oak - black oak - Northern red oak) forest cover type.

^bBird species demonstrates at least facultative use of tree cavities.

Appendix IX. Year 2001 individuals recorded in 50-meter point count plots in Monongahela National Forest, West Virginia. Numbers reflect maximum tally within each plot ($n=30$ for each forest type).

Common Name	Scientific Name	Forest Type ^a		
		S	N	C
Acadian flycatcher	<i>Empidonax virescens</i>	0	1	13
alder flycatcher	<i>Empidonax alnorum</i>	0	1	0
