ABSTRACT

Effect of Electron Beam Radiation on Microbial Inactivation, Radio-resistance and Nutritional Quality of Food

Adiam Tsegai Tesfai

A non-thermal food processing method, Electron beam radiation efficiently inactivates foodborne pathogens. However, foodborne pathogens may develop resistance in response to sub-lethal stresses. Thus it is important to study the response of food microorganisms to e-beam and understand the mechanism underlying their survival abilities. The overall objective of this study was to examine the inactivation of foodborne microorganisms by electron beam radiation at sub-lethal levels, understand the radio-resistance development to this processing method and also to determine the effects of e-beam on chemical changes of nutrients in infant formula.

Four independent studies are included in this dissertation, in the first study, development of radio-resistant *Salmonella* Typhimurium in egg as a microbial response to e-beam at sublethal levels was investigated and the D_{10} -value for *S. Typhimurium* was determined after repetitive processing with e-beam at sub-lethal doses. Survivors were enumerated on non-selective (TSA) and selective (XLD) media. Survivors from the highest dose were isolated and used in subsequent e-beam cycle. This process was repeated four times for a total of five e-beam cycles. D_{10} -values for *S. Typhimurium* ATCC strain 14028 were 0.59 ± 0.031 and 0.46 ± 0.022 kGy on TSA and XLD, respectively. However, following the fifth e-beam cycle, the respective D_{10} -values increased ($P < 0.05$) to 0.69 ± 0.026 and 0.61 ± 0.029 kGy. *S. Typhimurium* showed a trend ($P > 0.05$) to develop radio-resistance faster on selective media, likely due to facilitated selection of radio-resistant cells within microbial population following each e-beam cycle. For all five e-beam cycles, *S. Typhimurium* had higher ($P < 0.05$) D_{10} -values on non-selective media, indicating that sub-lethal injury followed by cellular repair and recovery are important for radio-resistance and inactivation of this microorganism.

To further investigate the radio resistance development of microorganisms to repetitive e-beam sublethal doses, in the second study DNA repair deficient *E. coli* DH5 α that have mutations

of *recA* and *gyrA* genes was used. The objective was to determine if repetitive processing with e-beam at sub-lethal doses increases D_{10} -value of *E. coli* DH5 α in ground beef. Five cycles of e-beam were conducted. D_{10} -values increased ($P<0.05$) significantly with each cycle. Following the third cycle D_{10} -values were 0.32 ± 0.006 and 0.32 ± 0.002 kGy for survivors enumerated on non-selective and selective media, respectively; the fourth cycle 0.39 ± 0.007 and 0.40 ± 0.019 kGy; and the fifth cycle 0.46 ± 0.006 and 0.46 ± 0.020 kGy. The result of the study indicates *E. coli* DH5 α increases radio-resistance to e-beam as a result of repetitive exposure to sub-lethal doses despite its DNA repair deficiency.

The third study investigated the role of *recA* and *gyrA* genes in *E.coli* DH5 α that had become resistant to repetitive e-beam radiation in the previous study and its ability to repair the damage caused by e-beam. Genomic DNA from *E.coli* DH5 α , radio-resistant A2 and A4 were extracted, and DNA fragments of the *gyrA* and *recA* genes containing the mutations were amplified, cloned and sequenced. *E.coli* DH5 α and radio-resistant A2 and A4 were compared to a reference genome for identification of nucleotide polymorphisms, insertions, and deletions that may have contributed to its radio- resistance. Results of the study demonstrated that *E.coli* DH5 α was able to reverse its mutation after sub lethal e- beam radiations. The study revealed that DNA repair deficient *E. coli* DH5 α increased radio-resistance to e-beam as a result of repetitive exposure to sub-lethal doses despite its DNA repair deficiency due to its ability to reverse its mutation. Understanding the resistance development of microorganisms is important in designing a food process control and efficacy of the processing method.

The last study examined the effect of e-beam on chemical changes of nutrients in infant formula. Dehydrated infant milk formula was processed with e-beam at 0 (control) to 25 kGy. Amino acid, fatty acid, and mineral profiles (AAP, FAP, and MP, respectively), as well as protein degradation and lipid oxidation, were determined. Our results demonstrate proteins, lipids, and minerals in infant milk formula were stable when processed with e-beam up to 25 kGy.

ACKNOWLEDGEMENTS

First and foremost, I thank God, for the endless blessings in my life, which have made me who I am today. I could never have done any of this without the faith I have in Him.

This dissertation appears in its current form due to the assistance and guidance of several people, which I would like to offer my sincere gratitude.

I am truly indebted and thankful to my supervisor Dr. Jacek Jaczynski, his guidance and encouragements throughout the project have been extremely helpful. His mentorship was paramount in providing a well-rounded experience consistent to my long-term career goals. Without his guidance this dissertation would not have been possible.

I also wish to extend my gratitude to my committee members, Dr. Janibo Yao, Dr. Janet Tou, Dr. Kristen Matak and Dr. Gary Bissonnette for their guidance in my research. Special thanks to Dr. Janibo Yao for his helpful discussion in Chapter 3.

Furthermore I would like to thank Sarah Beamer, for her assistance and her friendship during my entire stay at WVU. I will always be grateful to her assistance inside and outside of the lab. My colleagues Dr. Reza Tahergorabi, Lei Wang and Meghan Manor for their valuable discussion and assistance in the lab.

My sincerest thanks to all my friends, especially those in Morgantown, who made my stay, feel at home far away from home.

I am very much indebted to my family. Words cannot express how much each of you has done for me throughout my education and life; I appreciate everything you have done.

Last but not least, I thank my fiancé Ghideon Solomon whom I love with all my heart, for his unconditional love, support and patience.

LITERATURE REVIEW

1. Food Irradiation

Food irradiation is a process by which food is exposed to a defined dose of ionizing radiation under controlled conditions. It can be used for wide purposes, to reduce insect infestation of grain, dried spices, fruits and vegetables; inhibit sprouting in tubers and bulbs; retard postharvest ripening of fruits; inactivate parasites in meats and fish; eliminate spoilage microbes from fresh fruits and vegetables; extend shelf life in poultry, meats, fish, and shellfish; decontaminate poultry and beef; and sterilize foods and feeds (Arvanitoyannis, 2010). The words “irradiation” and “radiation” are often used interchangeably; however the word irradiation is a more general term referring to the exposure of food to radiation to achieve a technical goal where “radiation” describes a type of energy (Matak and Jaczynski, 2009). This exposure halts spoilage by retarding enzymic action or destroying microorganisms and it can also inactivate foodborne pathogenic organisms. Irradiation affects cells and microorganisms by damaging their DNA, breaking down cell membranes and interrupting enzymic pathways until organisms can no longer successfully continue the process of cell division. The major effect of irradiation is to generate short-lived and transient radicals (e.g. the hydroxy radical, the hydrogen atom and solvated electrons) that in turn damage DNA and intercellular structures.

Research on food irradiation dates back to the turn of the 19th century and the use of ionizing radiation for food preservation began in the early 1920s. The first US patent was obtained in 1921, on the use of x-ray to kill parasites in pork (Arvanitoyannis, 2010). The use of food irradiation increased after 1947 when researchers found that meat and other foods could be

sterilized by high energy. In the early 1950's, the U.S. Army began a series of experiments with fruits, vegetables, dairy products, fish and meats to establish the safety and effectiveness of irradiation (Wilkinson & Gould, 1996). It has been improved since then and it is the most studied food processing method to date (Diehl, 2002).

The energy of constituent particles or photons of ionizing radiation is expressed in electron volts (eV), or more conveniently in Million Electron Volts: MeV ($1 \text{ MeV} = 1.602 \times 10^{-13} \text{ J}$). Dosimetry is the measurement of absorbed radiation dose that is commonly referred as dose. Microbial inhibition by ionizing irradiation is a function of dose where “dose” describes the amount of radiation absorbed by the food product. The unit commonly used for dose is the Gray (Gy) or Joules per kilogram, where $1 \text{ Gray} = 1 \text{ Joule (J) of energy absorbed per kilogram (kg) of irradiated food}$ (Matak and Jaczynski, 2009; EFSA, 2011).

Irradiation is a safe process that leaves no residual radioactivity in the food and has been approved by over 50 countries worldwide (IFIC, 2002). Both FDA and USDA require irradiated food products be labeled with the international food irradiation symbol, the radura shown in Figure 1. and must contain the words "treated with radiation" or "treated by irradiation" on the packaging.

Food irradiation has proven to be an effective means of reducing the population of harmful biological contaminants and bacterial pathogens. Thus, United States government regulatory agencies have approved the use of irradiation processing of various foods. Low dose irradiation ($< 0.5 \text{ kGy}$) is used to kill fruit flies and other pests for disinfection; ($< 2 \text{ kGy}$) delay sprouting of vegetables and aging of fruits; medium doses ($1 - 10 \text{ kGy}$) is used to reduce the levels of bacterial pathogenic organisms, high dose ($> 10 \text{ kGy}$) is used to achieve sterility of

product (Komolprasert and Morehouse, 2004). Sterilization dose (> 42 KGy) is used to sterilize foods for patients with compromised immune systems and NASA astronauts (WHO, 1999).

2. Radiation Sources Used in Food Processing

The three types of ionizing irradiation sources allowed to be used in food irradiation applications are Gamma rays, electron beam radiation and X-rays. The source of Gamma rays is from radioactive nuclides, e-beam radiation from energetic electrons of particle accelerators and X-rays emitted by high-energy electron beams (Codex Alimentarius Commission (CAC), 2003). These types of radiation are called “ionizing” because their energy is high enough to dislodge electrons from atoms and molecules and to convert them to electrically charged particles called ions (EFSA, 2011). Electron beam radiation, one of the radiation sources is unitized for use in this dissertation.

E- beam radiation

Electron radiation (e-beam) is a process that involves using electrons to treat an object for a variety of purposes. E-beam utilizes high-energy electrons for pasteurization or sterilization effect in contrast to thermal and high-pressure types of food processing. Electron beams traveling at nearly the speed of light are produced from accelerators, such as in a linear accelerator or a Van de Graaff generator. The maximum e- beam energy allowed for food processing is 10 MeV. Research demonstrates that foods irradiated with accelerated electrons with energies of less than 10 MeV, will not induce radioactivity in foods (WHO, 1981).

When processing food with e- beam radiation, electrons are accelerated to the speed of light by a linear accelerator and transferred to an e-beam gun, which subsequently passes high-

energy electrons onto the food that is subjected to processing, resulting in microbial inactivation. Depending on the e-beam dose, pasteurization or sterilization can be achieved. E-beam radiation is a non-thermal food processing and does not alter the temperature of processed food (Jaczynski and Park, 2003). Therefore, food quality degradation due to heat is not a concern for e-beam processing.

The electron source in e- beam is electricity (Diehl, 1995) and, unlike gamma radiation, e-beam does not use radio-isotopes and create radioactive waste. Recently e-beam irradiation has become more common than gamma irradiation as e-beam does not require replenishment of the source as does cobalt-60 to produce radiation and they can be turned on only as needed (Tahergorabi et al., 2012). While the overall antimicrobial properties of gamma radiation and e-beam are comparable, e-beam enables application of high dose rates (e-beam, $10^3 - 10^5$ Gy/sec; gamma, 0.01–1 Gy/sec), resulting in a shorter processing time. However, e-beam, unlike gamma radiation, has a limited penetration depth. The high-energy electrons can effectively penetrate approximately 2 inches in typical food products and consequently inactivate foodborne pathogens (Jaczynski and Park, 2003). Therefore, the size and dimensions as well as specific density of food products should be carefully considered prior to e-beam processing. The e-beam dose is the quantity of radiation energy absorbed by food as it is subjected to e-beam processing (Tahergorabi et al., 2012).

3. Microbial Inactivation from e-beam radiation

Ionizing radiation including e-beam inactivates microorganisms by dual action involving lethal DNA changes (direct effects) and free radicals generated during water radiolysis (indirect effects). The direct effects are due to the breakage of chemical bonds between base pairs within

microbial DNA resulting in reproductive death of microorganisms. It can induce both single stranded and double stranded breaks of DNA. The direct effect of e- beam microbial inactivation is described in Figure 2. The indirect effects occur when free radicals from ionization of water molecules disintegrate the microbial cell membrane.

The radiolysis of water products includes the hydroxyl radical, hydrogen atom, and hydrated electron (Urbain, 1986). The hydroxyl radical is the most important of all, 90% of the damage is due to hydroxyl radicals formed in the hydration layer around the DNA molecule (Farkas, 1988; Asad et al., 2004). The indirect radiation damage is predominant in living cells, resulting in a break in the phosphodiester backbone in one strand of the molecule (single-strand break) or in both strands at the same place (double-strand break) (Farkas, 1997). Irradiation also damages membrane structure, which interferes with the normal metabolism of cells, such as generation of energy, and inhibits cell growth and eventually leads to cell death (Farkas, 1988).

It is generally believed that DNA is the most critical target of ionizing radiation and inactivation of microorganisms by ionizing radiation is a result of damage to their DNA (WHO, 1988). When a population of microorganisms is irradiated, a proportion of the cells will be damaged or killed, depending on the dose. A common measure of the radiation sensitivity in bacteria is the D_{10} value, which is the radiation dose required to achieve one log cycle or 90% reduction of the initial microbial population (Urbain, 1986).

The survival of microbial cells upon irradiation depends on the nature and extent of direct damage produced inside the cell, the number, nature, longevity of irradiation-induced reactive species, and the inherent ability of cells to withstand the assaults and undergo repair. The DNA repair mechanism is a universal stress response following irradiation (Fitt and Sharma, 1991).

Extracellular conditions such as pH, temperature, and chemical composition of the food in which microorganisms are suspended have very strong impact on the survival of microorganisms upon irradiation.

Generally, radiation injured microorganisms may lose their ability to proliferate under nutrient limited conditions where uninjured microorganisms can survive. Several physical stresses that have been demonstrated to cause potentially lethal damage include: heat, cold, drying, freeze-drying, freezing, irradiation. One of the most significant characteristics of injured organisms is their temporary inability to grow on selective media. This is significant because selective media are commonly employed for the enumeration of viable bacteria, including pathogens, as a means of assessing the efficacy of a food process. The inability of some injured organisms to grow on selective media has been associated with lesions in the cellular membrane (Lucht, 1998).

4. Microbial Radio-resistance

Ionizing radiation affects cells and microorganisms by damaging their DNA beyond its ability to repair, breaking down cell membranes and interrupting enzymatic pathways. An organism's radiation resistance (radio-resistance) is defined by the maximum dose it can survive (Daly, 1994). The integrity of chromosomal DNA must be conserved following exposure to radiation to ensure survival. When microorganisms are treated with DNA damaging agents they stop DNA replication by blocking movement of polymerase along a template strand (Barista, 1997; Mostafavi, 2012). Generally, it is believed microorganisms that are capable of repairing the breaks induced by ionizing radiation are radiation resistant whereas microorganisms that are sensitive to radiation cannot repair double-strand breaks (WHO, 1981). Understanding the

resistance of microorganisms to radiation is very important in order to determine the efficacy of irradiation on food products.

Radiation sensitivity of organisms increases with the complexity of an organism. Differences in radiation sensitivities within groups of similar organisms are related to differences in their chemical and physical structure and the ability to recover from radiation injury (Murano and Hayes, 1995).

Radiation resistant microorganisms have earned a great deal of attention in order to understand the mechanism underlying their survival. The mechanism of radiation resistance was studied in one of the most radiation resistant bacteria, *Deionococcus radiodurans*. The extreme resistance development of *D. radiodurans* has been attributed to its efficient DNA repair ability after it is damaged by ionizing radiation (Makarova et al., 2001). For damaged DNA to be repaired with the help of an intact homologous sequence, the two DNAs need to find each other among numerous unrelated sequences and trade strands to make possible one-strand repair of the damage in the affected sequence (Kuzimanov, 1999).

Krisko and Miroslav (2011) reported cell death by radiation is caused primarily by oxidative damage with consequential loss of maintenance activities including DNA repair. They suggested oxidative damage to proteins might also contribute to the killing of cells exposed to radiation (Krisko and Miroslav, 2011). Radio-resistance can also be attributed to effective system of anti-oxidant protection of cellular constituents, including those required for double-strand repair in order to continue reproducing after doses of radiation causing hundreds of double strand breaks per nucleus (Krisko et al., 2012).

Microorganisms that survive a given stress often can gain resistance to that stress or other

stresses via cross-protection or various other mechanisms (Wesche et al., 2009). Several environmental stress and food preservation methods are known to induce adaptive responses within the bacterial cell. Thus, it is important to study the response of microorganisms and their mechanism to food processing techniques.

5. Effect of E-beam on Nutritional Quality of Food

The safety and nutritional adequacy of food irradiation has been extensively studied, following comprehensive review, the Joint Expert Committee on Food Irradiation representing FAO/IAEA/WHO (Food and Agriculture Organization/International Atomic Energy Agency/World Health Organization) concluded that irradiation of any food up to 10 kGy causes no toxicological hazards and introduces no nutritional or microbiological problems (WHO, 1981). Based on their review, macronutrients such as carbohydrates, proteins, and fats are not largely affected by ionizing radiation even at doses over 10 kGy. According to the Institute of Food Technologists' Expert Panel on Food Safety and Nutrition, nutrient losses associated with irradiation are less than those associated with cooking or many other food-processing methods. The impact of irradiation on the food nutritional quality depends on the kind of food, radiation dose, the packaging atmosphere, the temperature during irradiation processing and post-irradiation storage, the presence or the absence of oxygen, and the storage time (Stefanova et al., 2010).

Chemical changes can occur via primary radiolysis or secondary indirect effects. Primary effects result due to direct absorption of energy by irradiated food while secondary indirect effect

is due to high reactivity of the free radicals and excited molecular ions produced from reactive intermediates. The free radical can undergo a variety of reactions leading to stable chemical products, often referred to as radiolytic products. Proteins when subjected to ionizing radiation absorb energy that leads to protein denaturation. Globular proteins irradiated in dilute solutions could undergo aggregation (Diehl, 1995).

Irradiation can produce protein radiolysis, which may cause the formation of free amino acids (Erkan and Ozden, 2007). It can also change the structure of a protein, primarily by breaking hydrogen bonds and other linkages in the long chains that make up proteins. Gamma irradiation of hazelnuts at 10 kGy induced aggregation and denaturation of proteins resulting in moderate effects on the protein structure (Dogan et al., 2007). Hein et al. (2000) have also reported radiation-induced change in amino acids. The dose applied determines the effect; a high dose will change the primary structure while moderate doses will affect the secondary and tertiary structures (Arvanitoyannis, 2010). Proteins absorb less energy when subjected to ionizing radiation than heat. Thus, proteins denature significantly less when subjected to ionizing radiation than to heat (Venugopal et.al, 1999).

Several chemical reactions can be produced due to irradiation of lipids. The lipid concentration, physical status (liquid or solid), and unsaturation profile determines the intensity radiation effect (EFSA, 2011). Ionizing radiation induced radiolysis of water can also generate free radicals such as $\text{OH}^\cdot$, H^+ and hydrated electron, all of which react with the food constituents. Since the hydroxyl radical is an oxidizing agent and the hydrated electron is the reducing agent, free radical oxidizing and reducing reactions can be expected in food. The most susceptible site for free radical attack in a lipid molecule is adjacent to the double bonds. Thus the most affected

lipids during irradiation are thus the polyunsaturated fatty acids that bear two or more double bonds (Oraei et al., 2011). Irradiation has been reported to accelerate lipid oxidation (Stewart, 2001). Lipid oxidation effect is more relevant in foods with larger fat content and high-unsaturated fatty acids content due to free radicals formed during irradiation. Using low temperature during processing and reducing the presence of oxygen can minimize lipid oxidation (Stefanova et al., 2010).

Similar to several thermal food processing methods, losses of vitamins can be caused by e- beam radiation. The radiation sensitivity of vitamins decreases in the following sequences (Diehl, 1995; Stefanova et al., 2010): Fat-soluble vitamins: vitamin E > carotene > vitamin A > vitamin D > vitamin K. Water-soluble vitamins: vitamin B1 > vitamin C > vitamin B6 > vitamin B2 > folate, niacin, vitamin B. Electron beam radiation affects the nutritional quality of food depending on doses applied, temperature during processing and type of food.

Organization of the dissertation

Chapter 1, 2 and 3 will discuss about the effect of e- beam on microbial inactivation and radio-resistance development of food-borne microorganisms to e- beam.

Chapter 4 will discuss the effect of e-beam on chemical changes of nutrients in infant formula.

CHAPTER 1

Microbial Radio-resistance of *Salmonella* Typhimurium in Egg Increases Due to Repetitive Irradiation with Electron Beam

Adiam T. Tesfai, Sarah K. Beamer, Kristen E. Matak, and Jacek Jaczynski

Radiation Physics and Chemistry (2011), 80, 591-596.

1.1 Abstract

Ionizing radiation improves food safety. However, foodborne pathogens develop increased resistance in response to sub-lethal stresses such as heat, pH, antibiotics, etc. Therefore, it is hypothesized that foodborne pathogens may develop increased radio-resistance to electron beam (e-beam) radiation. The objective was to determine if D_{10} -value for *Salmonella* Typhimurium in de-shelled raw egg (egg white and yolk mixed together) increases due to repetitive processing with e-beam at sub-lethal doses. Survivors were enumerated on non-selective (TSA) and selective (XLD) media. Survivors from the highest dose were isolated and used in subsequent e-beam cycle. This process was repeated four times for a total of five e-beam cycles. D_{10} -values for *S. Typhimurium* enumerated on TSA and XLD following each e-beam cycle were calculated as inverse reciprocal of the slope of survivor curves. D_{10} -values for the ATCC strain were 0.59 ± 0.031 and 0.46 ± 0.022 kGy on TSA and XLD, respectively. However, following the fifth e-beam cycle, the respective D_{10} -values increased ($P < 0.05$) to 0.69 ± 0.026 and 0.61 ± 0.029 kGy. *S. Typhimurium* showed a trend ($P > 0.05$) to develop radio-resistance faster on selective media, likely due to facilitated selection of radio-resistant cells within the microbial population following each e-beam cycle. For all five e-beam cycles, *S. Typhimurium* had higher ($P < 0.05$) D_{10} -values on non-selective media, indicating that sub-lethal injury followed by cellular repair and recovery are important for radio-resistance and inactivation of this microorganism. This study demonstrated that e-beam efficiently inactivates *S. Typhimurium* in raw egg; however, similar to other inactivation techniques and factors affecting microbial growth, *S. Typhimurium* develops increased radio-resistance if repetitively processed with e-beam at sub-lethal doses.

Key words: *S. Typhimurium*, electron beam, food irradiation, microbial inactivation kinetics, non-thermal food preservation, and microbial inactivation.

1.2 Introduction

Contamination of food products with *Salmonella* poses a public health problem and is a cause of foodborne illness worldwide (Bell and Kyriakides, 2002; Farkas, 1998; Sarjeant et al., 2005). There are more than 2,500 serotypes of *Salmonella* reported, but *Salmonella enterica* subsp. *enterica* serotype Typhimurium (*S. Typhimurium*) is the number one leading serotype-causing salmonellosis worldwide (Brenner et al., 2000; Galanis et al., 2006). *S. Typhimurium* is often found in many food products, but the most common sources are poultry, cheese, and eggs (Centers for Disease Control and Prevention, 2009a). According to the CDC report, every year in the U.S. approximately 40,000 people are reported ill due to salmonellosis (Centers for Disease Control and Prevention, 2009a). There have been several recent high-profile outbreaks of foodborne salmonellosis the United States. These outbreaks implicated food products that had not been commonly thought of as typical transmission vehicles for *S. Typhimurium*. For example, the CDC has reported 529 confirmed cases in 43 states implicating peanut butter and peanut butter containing products (Centers for Disease Control and Prevention, 2009b). The increasing incidence of *S. Typhimurium* in different food products may be associated with the adaptability of this microorganism to various unfavorable conditions (Anriany et al., 2001).

Ionizing radiation as a non-thermal means to improve microbial food safety has received considerable attention. Electron beam (e-beam) irradiation is highly effective for inactivating foodborne pathogenic microorganisms (Black and Jaczynski, 2006; 2007; 2008; Jaczynski and Park, 2003a; Levanduski and Jaczynski, 2008; James et al., 2010; Hvizdzak et al., 2010). As with other types of ionizing radiation such as gamma and X-rays, e-beam inactivates

microorganisms directly by lethal damage of microbial DNA and indirectly by free radicals generated during water radiolysis that disintegrate microbial cell membrane (Urbain, 1986). E-beam inactivates pathogens non-thermally; and therefore, may be used to inactivate *Salmonella* in raw egg (Alvarez et al., 2007). Although dependent on a particular food product, e-beam does not affect protein functionality and other food quality attributes within typical doses required for microbial inactivation (Jaczynski and Park, 2003b; 2004).

Adaptation of *S. Typhimurium* to various stresses has been reported in literature. *S. Typhimurium* can adapt to several environmental stresses at sub-lethal levels such as nutrient starvation, pH extremes, oxidative stress, osmotic shock, and heat shock (Foster and Spector, 1995). It has been demonstrated that acid-adapted *S. Typhimurium* develops cross-protection, resulting in increased tolerance against other environmental stresses (Leyer et al., 1993). This may be influenced by changes in properties of cell surface due to the synthesis of specific outer membrane proteins (i.e., shock proteins). The acid shock proteins are expressed as a microbial response to stressful pH conditions and result in increased acid tolerance. This has been associated with enhanced resistance to heat and osmotic stress (i.e., cross-protection) (Leyer et al., 1993). The acid adaptation/tolerance has also been associated with cross-protection against ionizing radiation, resulting in increased radio-resistance of *Escherichia coli* O157:H7 (Buchanan et al., 1998; 1999; 2004). Development of increased microbial resistance to antibiotics resulting in cross-protection against e-beam has also been suggested for nalidixic acid resistant *Salmonella enterica* subsp. *enterica* serotype Montevideo (James et al., 2010). A possibility of development of radio-resistant *Salmonella* (a major foodborne pathogen worldwide) in egg (staple food worldwide) as a microbial response to e-beam (novel non-thermal antimicrobial processing technology) at sub-lethal levels is unknown. To our knowledge there

have been no published reports in this area. Therefore, it is critical to study this microbial behavior in food as it has both, practical meaning and scientific significance.

It is hypothesized that *S. Typhimurium* will develop increased ($P < 0.05$) radio-resistance in egg if exposed repetitively to e-beam processing at sub-lethal doses. The objective of this challenge study was to determine if repetitive exposure to e-beam at sub-lethal doses increases ($P < 0.05$) D_{10} -value for *S. Typhimurium* in de-shelled raw egg (egg white and yolk mixed together).

1.3 Materials and methods

1.3.1 Sample preparation

Fresh raw eggs were purchased from a local supermarket. Preliminary tests (data not shown) confirmed that *Salmonella* was below detectable levels in eggs used in this study. Egg shells were thoroughly cleaned followed by sanitation with 70 % ethanol and allowed to air dry under UV in a bio-safety cabinet (Class II Type A/B3, NuAire, Inc., Plymouth, MN). Sanitized eggs were aseptically broken, transferred into a laboratory blender (model S13L31, Waring Laboratory, Torrington, CT) and homogenized for 1 min. The egg sample prepared in this manner will hereafter be called de-shelled raw egg. All equipment used to handle the eggs such as blenders, spatulas, etc. was cleaned and sanitized with ethanol, followed by drying under UV in the bio-safety cabinet. Whenever applicable, aseptic technique under bio-safety cabinet was used for transfer, handling, etc. of *Salmonella*.

1.3.2 Microorganism and culture conditions

Salmonella enterica subsp. *enterica* serotype Typhimurium ATCC strain 14028 (hereafter called *S. Typhimurium*) was used in this study (Brenner et al., 2000). *S. Typhimurium* lyfo-disks were reconstituted by crushing one pellet using sterile spatula in 0.4 mL of sterile trypticase soy broth (TSB) (Becton Dickinson and Company, Sparks, MD). The content was aseptically transferred to 3.6 mL of sterile TSB and allowed to grow aerobically at 35°C for 24 h in an incubator/shaker set at 150 rpm (C24 Incubator/Shaker, New Brunswick Scientific, Edison, NJ). The 4 mL *S. Typhimurium* culture was aseptically transferred to 76 mL of sterile TSB and allowed to grow aerobically at 35°C for 24 h in the incubator/shaker set at 150 rpm. Preliminary studies (data not shown) confirmed that this procedure yielded a *S. Typhimurium* culture at stationary phase of growth and approximately 10^9 CFU/mL.

The 24-h *S. Typhimurium* culture was used as an inoculum for the de-shelled raw egg. Inoculum was added to the egg at 5% (v/v). Following inoculation, the de-shelled raw egg (egg white and yolk mixed together) was aerobically incubated (Isotemp Incubator, Fisher Scientific, Pittsburgh, PA) at 35°C for 24 h. Preliminary studies (data not shown) verified that this procedure resulted in a concentration of *S. Typhimurium* at approximately 10^9 CFU/mL of de-shelled raw egg. Distilled and de-ionized water (ddH₂O) was periodically added to account for moisture loss due to evaporation during incubation and the sample was periodically mixed to ensure adequate distribution of microbial cells in the de-shelled raw egg.

Following incubation, individual samples of approximately 12 g of inoculated de-shelled raw egg were separately packed (10 x 15 cm Kapak SealPAK pouches, Kapak Corporation, Minneapolis, MN) and aerobically sealed (Kapak sealer, Kapak Corporation, Minneapolis, MN). Each sample was spread evenly, resulting in a thickness below 1 mm in order to ensure complete

penetration of e-beam and even distribution of absorbed dose throughout the sample (Jaczynski and Park, 2003a). The samples were stored at -80°C until shipment. The storage time did not exceed one week.

1.3.3 Treatment

Samples were packed and shipped according to an approved institutional protocol in a heavy-duty styrofoam cooler filled with dry ice. Samples were shipped overnight to an e-beam processing facility (Sterigenics International, San Diego, CA). At the e-beam facility, the samples were allowed to equilibrate to 4°C overnight in a refrigerator prior to e-beam processing. The samples at refrigeration temperature (4°C) were subjected to one-sided e-beam with energy fixed at 10 MeV and doses between 0.0-4.0 kGy were applied. The applied e-beam doses were confirmed with film dosimeters (Jaczynski and Park, 2003a). The film dosimeters (FWT-60 series radiochromatic dosimeters, Far West Technology, Inc., Goleta, CA) were attached to the bottom of the Kapak pouches prior to e-beam processing. The absorbed doses were determined following e-beam processing at 605 nm using a spectrophotometer (Cary 100 UV-Vis, Varian, Inc., Palo Alto, CA). The absorbed doses were used to calculate D₁₀-values.

Immediately following e-beam treatment, samples were frozen, packed, and shipped overnight back to the food microbiology laboratory at West Virginia University. Upon arrival, the e-beam processed samples were stored at -80°C until analysis. The storage time did not exceed one week. Preliminary studies (data not shown) determined that the freeze-thaw cycles used in the experiments did not ($P>0.05$) affect the survival of *S. Typhimurium*; and therefore, did not confound the results. All of the experiments had samples that were not exposed to beam (i.e., 0.0 kGy). These samples were used as control samples. The control samples received the

same treatment as all other samples except for e-beam irradiation; i.e., they were shipped to the e-beam facility in the same heavy-duty styrofoam cooler and stored under the same conditions, but were not irradiated with e-beam. Three separate e-beam experiments ($n = 3$) were conducted.

*1.3.4 Bacterial enumeration of *S. Typhimurium* survivors*

The samples were equilibrated to 4°C overnight in a refrigerator prior to enumeration. The e-beam processed samples were manually pummeled for 1 min followed by mixing in a stomacher (Bag Mixer 400, Interscience, St. Nom, France) set at medium speed for 1 min in order to obtain equal distribution of survivors within the Kapak pouch. For serial dilutions, 10 g of each e-beam processed sample was aseptically placed into 90 mL of diluent (Butterfield phosphate buffer, Hardy Diagnostics, Santa Maria, CA). Further serial dilutions were aseptically made by taking 10 mL of diluted sample and transferring it into a 90 mL diluent bottle, followed by shaking the bottle to uniformly distribute survivors. Survivors were enumerated on non-selective (Tryptic-Soy Agar, TSA) (Becton Dickinson and Company, Sparks, MD) and selective (Xylose-Lysine-Deoxycholate agar, XLD) (Thermo Fisher Scientific Remel Products, Lenexa, KS) media using a standard spread-plating technique. An aliquot of 0.1 mL of each serial dilution was pipetted and spread on the TSA and XLD plates. The plates were incubated at 35°C for 24 h and discrete *Salmonella* colonies were counted. All bacterial enumerations were performed in duplicate and the mean values are reported as CFU/g.

*1.3.5 Isolation of *S. Typhimurium* survivors for repetitive e-beam processing*

Following the 24-h incubation on the TSA and XLD plates, colonies of *S. Typhimurium* survivors from the highest e-beam dose that resulted in survival were randomly isolated

separately from the TSA and XLD plates. Therefore, two separate isolates of *S. Typhimurium* were obtained. One isolate was from TSA plates, while the second isolate was from the XLD plates. The highest dose applied in the present study was 4 kGy; however, there were no detectable survivor colonies at that dose. Survivor colonies were isolated from the highest dose that resulted in survival of *S. Typhimurium*, which was lower than 4 kGy (i.e., the highest dose applied). The isolates from TSA and XLD plates were separately incubated in sterile TSB as previously described in “Microorganism and culture conditions”.

As described in “Sample preparation”, the 24-h *S. Typhimurium* cultures were used as inocula for the next sample of the de-shelled raw egg and cycle of e-beam processing. The isolation of *S. Typhimurium* survivors following e-beam processing was repeated four times and a total of five cycles of e-beam processing were conducted. In the first cycle of e-beam processing, the ATCC *S. Typhimurium* strain 14028 was used. The *S. Typhimurium* survivors isolated following the first cycle of e-beam processing were designated as A1 (hereafter called isolate A1), while the *S. Typhimurium* survivors isolated following the second cycle of e-beam processing using isolate A1 were designated as A2 (hereafter called isolate A2). Isolates A3 and A4 were obtained accordingly.

1.3.6 Determining D_{10} -values

Following each cycle of e-beam processing, the counts of *S. Typhimurium* survivors enumerated on TSA and XLD plates were separately plotted on a logarithmic scale as a function of e-beam dose (kGy). Therefore, for each cycle of e-beam processing two sets of separate survivor curves were constructed. One set of survivor curves corresponded to *S. Typhimurium* survivors enumerated on TSA (non-selective media) plates, while the second set to survivors

enumerated on the XLD (selective media) plates. Each set had three individual curves that were used to determine three D₁₀-values (three D₁₀-values for TSA and three D₁₀-values for XLD). The D₁₀-values were determined by calculating the negative reciprocal of the slope of the survivor curves (equation 1) (Jaczynski and Park, 2003a). D₁₀-value is recognized as the radiation dose required to achieve one log cycle or 90% reduction of the initial microbial population (Urbain, 1986).

$$\log\left(\frac{N}{N_0}\right) = -\frac{1}{D} * t \quad \text{..... Equation 1}$$

N – concentration of survivors after e-beam dose,

N₀ – initial microbial concentration,

D – D₁₀-value, decimal reduction dose,

t – e-beam dose.

1.3.7 Statistics

Five cycles of e-beam processing were conducted, three separate experiments (n = 3) per each cycle. The de-shelled raw egg samples were randomly assigned to e-beam doses. All bacterial enumerations in each of the three separate experiments were performed in duplicate and the mean values of the duplicate counts are reported as CFU/g. The mean values of the duplicate counts in each of the three separate experiments were log-converted and analyzed by linear regression using MS Office Excel software (Version 2007) in order to determine three D₁₀-values. One-way analysis of variance (ANOVA) was performed to detect significant differences in microbial survival with increasing e-beam dose. The PROC GLM software was used to

determine significant differences between mean D_{10} -values for *S. Typhimurium* enumerated on TSA and XLD media within each cycle of e-beam processing (Figures 1-5). The same software was used to determine significant differences between mean D_{10} -values for *S. Typhimurium* following all cycles of e-beam processing within each media type (Figure 6, Table 1). All statistical analyses were performed using SAS (Version 9) and differences were considered significant when $P < 0.05$ (SAS Institute, 2002).

1.4. Results and discussion

Survivor curves were plotted for *S. Typhimurium* ATCC strain 14028 (Figure 1) and each successive isolate (A1, A2, A3, and A4) following repetitive exposure to e-beam (Figures 2-5). Linear regression analysis of survivor curves yielded high correlation coefficients (R^2). In addition, ANOVA analysis showed that the log-converted counts of *S. Typhimurium* survivors decreased ($P < 0.05$) as the e-beam dose increased for all five cycles on both TSA and XLD media. Therefore, D_{10} -values for each isolate and the original ATCC strain were calculated from the survivor curves as a function of e-beam dose (Table 1). The ATCC strain had not been subjected to e-beam radiation prior to this experiment and the respective D_{10} -values were the lowest at 0.59 ± 0.031 kGy on TSA and 0.46 ± 0.022 kGy (Figure 1) on XLD. The highest ($P < 0.05$) D_{10} -values on TSA (0.69 ± 0.026 kGy) and XLD (0.61 ± 0.029 kGy) were determined for the isolate A4 following the fifth cycle of e-beam processing (Figure 5). These results prove that *S. Typhimurium* has the capability to develop increased ($P < 0.05$) radio-resistance if repetitively exposed to e-beam. Microbial radio-resistance increased by 117% and 133% for survivors of isolate A4 enumerated on TSA and XLD, respectively when compared to the original *S. Typhimurium* ATCC strain. Furthermore, the selective media (XLD) allowed faster increase of

radio-resistance than non-selective media (TSA), although it was a not significant ($P=0.058$) trend (Figure 7).

D_{10} -value of 0.44 ± 0.04 kGy for *S. Typhimurium* irradiated with ^{60}Co in the de-shelled raw egg has been reported (Alvarez et al., 2007). D_{10} -value of 0.53 ± 0.031 kGy for *S. Typhimurium* irradiated with ^{137}Cs under aerobic conditions in mechanically deboned chicken has also been reported (Thayer et al., 1990). Similar D_{10} -values were also determined in the present study ranging from 0.46 ± 0.022 kGy for *S. Typhimurium* ATTC 14028 in the de-shelled raw egg enumerated on XLD media to 0.69 ± 0.026 kGy for isolate A4 enumerated on TSA (Table 1). However, in the present study e-beam was used instead of gamma radiation and *S. Typhimurium* ATTC 14028 showed a development of increased ($P<0.05$) radio-resistance as response to repetitive e-beam irradiation.

Figure 6 shows the development of increased radio-resistance in the original ATCC strain and each successive isolate derived from this strain with respect to the enumeration on both media (i.e., TSA and XLD). The ANOVA analysis proved that the more microorganisms were subjected to e-beam processing, the greater ($P<0.05$) was their radio-resistance (i.e., D_{10} -value) to e-beam (Figure 6). For both TSA and XLD media, the PROC GLM analysis indicated that the second cycle of e-beam processing yielding isolate A1 resulted in D-values that were not ($P>0.05$) different from D_{10} -values for the ATCC strain and isolate A2. However, there was a significant increase ($P<0.05$) of the D_{10} -values between isolates A1 and A3 as well as A4 enumerated on both types of media (Figure 6). Many studies have demonstrated that *S. Typhimurium* responds to stressful environmental conditions with physiological changes that enhance microbial survival (Foster and Spector, 1995; Humphrey, 2004; Karatzas et al., 2008). Exposure of *S. Typhimurium* to repetitive cycles of acid challenge increased microbial resistance

to acid and additionally triggered development of heat adaptation in one line of the isolates (Karatzas et al., 2008). It has been shown that acid-adapted *S. Typhimurium* cells increase heat resistance (Leyer and Johnson, 1993) and radio-resistance (James et al., 2010). Therefore, it has been theorized that acid habituation may synergistically increase microbial radio-resistance to ionizing radiation, resulting in cross-protection (Buchanan et al., 2004). The cross-protection of acid-adapted *S. Typhimurium* may be influenced by changes in cell surface properties due to the synthesis of specific outer membrane proteins (Leyer and Johnson, 1993). It is likely; therefore, that the repetitive exposure of *S. Typhimurium* to e-beam in the present study triggered similar microbial response mechanism resulting in changes of cell surface properties; and consequently, might have contributed to the development of increased radio-resistance.

When *S. Typhimurium* survivors were enumerated on nutrient-rich non-selective media (TSA) allowing recovery of injured cells, the resultant D_{10} -value were greater ($P < 0.05$) for all five cycles when compared to the selective media (XLD) (Figures 1-5). The comparison between D_{10} -values for microorganisms enumerated on selective vs. non-selective media allows determination of whether or not e-beam resulted in the sub-lethal injury and cellular repair of *S. Typhimurium* survivors (Ray, 1979). The consistently higher ($P < 0.05$) D_{10} -values in the present study for *S. Typhimurium* enumerated on TSA than on XLD following all five e-beam cycles (Figures 1-5) indicate that e-beam resulted in the sub-lethal injury of some of the cells. Furthermore, as evidenced by the higher counts on the TSA plates, this injury was not sustained, but instead some of the survivors repaired cellular damage, recovered and grew on the TSA plates. Therefore, the results of the present study demonstrate that e-beam similarly to gamma irradiation (^{60}Co) of *S. Typhimurium* in chicken meat results in inactivation as well as cellular injury (Lamuka et al., 1992). Alvarez et al. (2007) inoculated de-shelled raw egg with *S.*

Enteritidis, *S. Typhimurium*, and *S. Senftenberg* that were subjected to gamma radiation (^{137}Cs) followed by heat treatment. As opposed to other reports (Lamuka et al., 1992; Sarjeant et al., 2005) as well as the present study, Alvarez et al. (2007) did not ($P>0.05$) observe irradiation-induced cell injury. However, the difference may be partially explained by different selective medium used by Alvarez et al. (2007). In the present study, XLD was used as a selective medium, whereas Alvarez et al. (2007) used 3% (w/v) NaCl supplement in the TSA medium (TSA-SC) as a selective factor for *Salmonella*. However, it has been demonstrated that *Salmonella* adapts to osmotic shock (i.e., ionic stress – NaCl) as well as develops cross-protection when stressed osmotically (Foster and Spector, 1995; Leyer and Johnson, 1993). Additionally, e-beam was used in the present study instead of ^{137}Cs . Gamma irradiation with ^{137}Cs had a dose rate of 0.095 kGy/min (1), which is about 1000-fold slower than typical e-beam such as in the present study. Some studies have demonstrated that dose rate has an effect on the rate on microbial inactivation. Since there was no ($P>0.05$) difference between D_{10} -values determined on TSA and TSA-SC, the average D_{10} -values for *S. Enteritidis*, *S. Typhimurium*, and *S. Senftenberg* were 0.50, 0.43, and 0.64 kGy, respectively (Alvarez et al., 2007). These values are similar to the values in the present study and to the previously reported D_{10} -values for *Salmonella* (Monk et al., 1994; Sherry et al., 2004; Thayer et al., 1990).

Licciardello et al. (1969) demonstrated that gamma radiation (^{60}Co) of *S. Typhimurium*, *S. Newport*, *S. Thompson*, and *S. Heidelberg* induces radio-resistance. In this early study, the radio-resistant cells were described as “plumper” than their parent strains and showed a marked pleomorphism. Percent survival was determined as an indicator of the radio-resistance (Licciardello et al., 1969). However, D_{10} -value is a well established and widely recognized indicator of microbial resistance/inactivation rates. Statistical analysis was not performed in this

early study, either. In comparison, D_{10} -values as a standard kinetics of microbial inactivation were determined and statistically compared following each cycle of e-beam irradiation on both selective (XLD) and non-selective (TSA) media in the present study. Conversely, Licciardello et al. (1969) enumerated survivors on non-selective (TSYE – Tryptic-Soy-Yeast-Extract) agar, which only accounted for fully viable cells and not for radiation-injured ones. Therefore, gamma radiation induced injury and cellular repair could not be determined. Also, Licciardello et al. (1969) used ^{60}Co as a source of ionizing radiation, which provides slow dose rate. The much slower dose rate as compared to e-beam may allow for initiation of cellular repair mechanisms; and consequently, some recovery of injured cells. However, despite these differences between the present study and the early study by Licciardello et al. (1969), the present study proves the same trend that *S. Typhimurium* develops increased radio-resistance if repetitively exposed to e-beam.

Davis and Sinskey (1973) characterized a radio-resistant mutant *S. Typhimurium* LT2. This microorganism exhibited stepwise increase of radio-resistance to gamma and UV radiations. Similarly to Licciardello et al. (1969), the radio-resistant cells were generally larger and also contained 1.8-2.1 times more RNA and protein than parent cells, but DNA contents were similar. It was suggested that the development of radio-resistance was a result of selection that favored mutations leading to increased capacity to repair microbial DNA (Davis and Sinskey, 1973). For all five cycles of e-beam processing in the present study, *S. Typhimurium* had higher ($P < 0.05$) D_{10} -values when enumerated on TSA than XLD plates, indicating that sub-lethal injury, followed by cellular repair and recovery are important for radio-resistance of this microorganism. The radio-resistance was developed at a faster rate on XLD than TSA plates (Figure 7); although this trend was not significant ($P = 0.058$). Therefore, similar to Davis and Sinskey's (1973)

suggestion, the present study confirms importance of cellular repair mechanisms in microbial radio-resistance.

The direct mechanism of microbial inactivation due to ionizing radiation including e-beam involves DNA damage (Urbain, 1986). Therefore, exposure of *Salmonella* to radiation results in high frequency of mutations in DNA fragments responsible for repair and replication, particularly, in *rpoS* genes (i.e., RNA polymerase S) (LeClerc et al., 1996). Thus, changes in *rpoS* may be important in the development of increased radio-resistance of *S. Typhimurium* to e-beam. We intend to investigate this concept with micro-arrays and comparative genomic sequences analysis (CGSA). Micro-arrays use RNA for comparative surveys of large populations. In CGSA, DNA (not RNA) of radio-resistant *Salmonella* is compared to a reference genome for identification of nucleotide polymorphisms, insertions, and deletions that may have contributed to survival of *Salmonella* exposed to e-beam.

1.5 Conclusions

E-beam is a non-thermal process that may be an alternative method to efficiently control *S. Typhimurium* in egg. *S. Typhimurium* has been shown to develop increased resistance to a variety of stresses such as low pH, increased temperature and ionic strength, and antibiotics. Repetitive irradiation of *S. Typhimurium* ATCC 14028 inoculated in de-shelled raw egg (egg white and yolk mixed together) with e-beam resulted in an increase ($P < 0.05$) of D_{10} -values from 0.59 ± 0.031 to 0.69 ± 0.026 kGy when enumerated on TSA plates and 0.46 ± 0.022 to 0.61 ± 0.029 kGy on XLD plates. While e-beam can efficiently inactivate *S. Typhimurium* in food products including egg, similar to other inactivation techniques and environmental stresses, *S. Typhimurium* has a capability to develop increased radio-resistance if repetitively processed with e-beam. The D_{10} -values for *S. Typhimurium* enumerated on non-selective media (TSA) were

greater ($P < 0.05$) than on selective (XLD) media for all five cycles of e-beam irradiation, indicating that sub-lethal injury followed by cellular repair and recovery are important aspects of microbial inactivation with e-beam.

Acknowledgments

Special thanks to Sterigenics International for allowing us to use e-beam facility. Our appreciation extends to Carl A. Zinn and Richard Vallejo of Sterigenics for invaluable technical expertise with e-beam and Aunchalee Aussanasuwamakul for assistance with statistical analysis. This research was funded by the USDA Hatch program (project nr WVA00429).

CHAPTER 2

Radio-resistance development of DNA repair deficient *Escherichia coli* DH5 α in ground beef subjected to electron beam at sub-lethal doses

Adiam T. Tesfai, Sarah K. Beamer, Kristen E. Matak, and Jacek Jaczynski

International Journal of Radiation Biology, 87:6 (2011), pages 571-578

2.1 Abstract

Electron beam (e-beam) efficiently and non-thermally inactivates microorganisms in food by lethal DNA changes (direct effects) and free radicals from water radiolysis (in-direct effects). Non-pathogenic *E. coli* DH5 α is a microorganism that lacks DNA repair capability, resulting in high radio-sensitivity. Studying microbial inactivation of *E. coli* DH5 α repeatedly subjected to sub-lethal e-beam in ground beef may enhance understanding of microbial radio-resistance. Thus, the objective of this study was to determine if repetitive processing with e-beam at sub-lethal doses increases D-value of *E. coli* DH5 α in ground beef. Survivors from the highest e-beam dose were isolated and incubated in ground beef for the next cycle of e-beam processing. Five cycles were conducted. To acclimatize *E. coli* DH5 α , first two cycles used low doses. D-values were determined following the third cycle. D-values increased ($P < 0.05$) significantly with each cycle. Following the third cycle D-values were 0.32 ± 0.006 and 0.32 ± 0.002 kGy for survivors enumerated on non-selective and selective media, respectively; the fourth cycle 0.39 ± 0.007 and 0.40 ± 0.019 kGy; and the fifth cycle 0.46 ± 0.006 and 0.46 ± 0.020 kGy. D-values on non-selective and selective media were similar ($P > 0.05$) indicating absence of cell recovery in *E. coli* DH5 α . *E. coli* DH5 α increases radio-resistance to e-beam as a result of repetitive exposure to sub-lethal doses despite its DNA repair deficiency.

Keywords: *Escherichia coli*, electron beam, food irradiation, microbial inactivation, inactivation kinetics.

2.2 Introduction

Foodborne illness due to pathogenic *Escherichia coli* such as the serotype O157:H7 has had an unquestioned status in the United States since meat borne outbreak in 1982 (Jay et al. 2005). In 1997, a U.S. company voluntarily recalled almost 11.5-mln kg of ground beef after 20 illnesses had been associated with ground beef products contaminated with *E. coli* in Colorado. In 2002, there were 36 food recalls in the U.S. implicating pathogenic *E. coli*. All the 36 recall involved ground beef products. Individual recalls ranged in size from 9 to 19-mln kg. In 1999, there were 62,458 confirmed cases of foodborne illnesses due *E. coli*, resulting in 1,843 hospitalizations and 52 deaths. Not only are meat products contaminated with *E. coli* often implicated in the outbreaks, but a media publicized multi-state outbreak implicating contaminated spinach and lettuce was responsible for over 205 illnesses and 3 confirmed deaths in 2006 (U.S. Food and Drug Administration 2010). The above examples from public health statistics clearly illustrate the need for a comprehensive understanding of inactivation of *E. coli* in food, particularly meat.

Ionizing radiation effectively inactivates microorganisms including foodborne pathogens (Arvanitoyannis et al. 2009, O'Bryan et al. 2008, Farkas 1998, Black and Jaczynski 2008, 2007, 2006, Chalise et al. 2007, James et al. 2010, Hvizdzak et al. 2010, Matak et al. 2010). Therefore, application of ionizing radiation to food processing enables food manufacturers to increase microbial food safety and extend shelf life of food products. Instead of radioisotopes, e-beam uses high-speed electrons generated from electricity in a linear accelerator that are passed onto the food from e-beam gun. Since e-beam inactivates microorganisms non-thermally, it may be used to inactivate *E. coli* in fresh food products including ground beef without cooking it. Although dependent on a particular food product, e-beam does not affect protein functionality

and other food quality attributes within typical doses required for microbial inactivation (Jaczynski and Park 2004, 2003b). Ionizing radiation including e-beam inactivates microorganisms by dual action involving lethal DNA changes (direct effects) and free radicals generated during water radiolysis (indirect effects). The direct effects are due to the breakage of chemical bonds between base pairs within microbial DNA resulting in reproductive death of microorganisms, while the indirect effects occur when the radiolysed water molecules (i.e., free radicals) disintegrate microbial cell membrane (Urbain 1986).

Subjecting microorganisms to various stressors at sub-lethal levels such as nutrient starvation, pH extremes, hyperoxia, high ionic strength, heat shock, antibiotics, etc. may result in selection of isolates that are more resistant to the imposed stress (Humphrey 2004). Therefore, it is likely that foodborne pathogens may develop increased resistance to e-beam. The development of radiation resistant (or radio-resistant) isolates plays an important role in determining the effectiveness of e-beam processing for food products. Thus, understanding of the development of increased microbial radio-resistance is critical from both, a practical and scientific point of view.

Radio-resistance depends on the ability of microorganisms to repair the damage caused by irradiation to microbial DNA and cell integrity. *E. coli* employs gene *recA* to mediate recombination pathway to repair damage in the DNA strands. The *rpoS* gene has also been suggested as a crucial component of the DNA repair. If the *rpoS* gene is intact, *E. coli* develops greater resistance to various stressors (Arnold and Kaspar 1995). Genetic mechanisms are invariably involved in the development of increased resistance of *E. coli* to stress and they are likely as critical in microbial radio-resistance. Increased radio-resistance of *Salmonella* to γ -rays has also been attributed to enhanced DNA repair (Davis and Sinskey 1973).

Non-pathogenic *E. coli* DH5 α is a very radio-sensitive microorganism (Sommers and Rajkowski 2008). This *E. coli* contains mutations of the *recA* and *gyrA* genes that are necessary for DNA repair and replication. Therefore, *recA* and *gyrA* mutants have impaired ability to repair and recombine their DNA strands making the mutants sensitive to ionizing radiation, ultra violet (UV), and chemicals (Bridges 1971, Mount et al. 1975, Sedgwick and Bridges 1972, Sharan et al. 2007, Cox 2007, Orser et al. 1995, Kornberg and Baker 2005). Therefore, studying microbial inactivation kinetics of this DNA-repair deficient *E. coli* DH5 α in a staple food such as fresh ground beef will enhance understanding of microbial radio-resistance to e-beam and may indicate some other, genetic or non-genetic factors involved in radio-resistance.

It is hypothesized that despite its incapability to repair DNA, *E. coli* DH5 α will develop significant increase ($P < 0.05$) of radio-resistance in fresh ground beef if exposed repetitively to e-beam processing at sub-lethal doses. The objective of this challenge study was to determine if repetitive exposure to e-beam at sub-lethal doses increases ($P < 0.05$) D-value for *E. coli* DH5 α in fresh ground beef.

2.3 Materials and methods

2.3.1 Sample preparation

Fresh lean ground beef was purchased from a local grocery store and only this ground beef was used in this study. The ground beef was vacuum packed and stored at -80°C until needed. Preliminary tests (data not shown) confirmed that the total *coliform* counts in the ground beef sample were below detectable levels. All laboratory equipment used to handle ground beef such as spatulas, containers, etc. was autoclaved or cleaned and sanitized with ethanol, followed by drying under UV in the bio-safety cabinet (Class II Type A/B3, NuAire, Inc., Plymouth, MN,

USA). Whenever applicable, aseptic technique under the bio-safety cabinet was used for transfer, handling, etc. of *E. coli* DH5 α .

Escherichia coli DH5 α *luxS supE44 Δ lacU169 (ϕ 80dlacZ Δ M15) hsdR17 recA1 endA1 gyrA96 thi-1 relA1* (hereafter called *E. coli*) (Invitrogen Inc., Carlsbad, CA, USA) lyfo-disks were reconstituted by crushing one pellet using sterile spatula in 0.4 ml of sterile trypticase soy broth (TSB) (Becton Dickinson and Company, Sparks, MD, USA). The content was aseptically transferred to 3.6 ml of sterile TSB and allowed to grow aerobically at 35°C for 24 h in an incubator/shaker set at 150 rpm (C24 Incubator/Shaker, New Brunswick Scientific, Edison, NJ, USA). The 4 ml aliquot of the *E. coli* culture was aseptically transferred to 76 ml of sterile TSB and allowed to grow aerobically at 35°C for 18 h in the incubator/shaker set at 150 rpm. Preliminary studies (data not shown) confirmed that this procedure yielded an *E. coli* culture at stationary phase of growth and approximately 10⁹ colony forming units (CFU)/ml.

The 18-h *E. coli* culture was used as an inoculum for ground beef. Prior to inoculation, the ground beef sample was thawed overnight in a refrigerator and the inoculum was added at 5% (v/w) to a thawed sample of ground beef. Following inoculation, the ground beef sample was aerobically incubated (Isotemp Incubator, Fisher Scientific, Pittsburgh, PA, USA) at 35°C for 24 h. Preliminary studies (data not shown) verified that this procedure resulted in a concentration of *E. coli* at approximately 10⁹ CFU/g of ground beef. Distilled and de-ionized water (ddH₂O) was periodically added to account for moisture loss due to evaporation during incubation and the sample was periodically mixed to ensure even distribution of microbial cells in the meat sample.

Following incubation, 18 individual samples of approximately 12 g each of inoculated beef were separately packed (Kapak SealPAK pouches, Kapak Corporation, Minneapolis, MN,

USA) and aerobically sealed (Kapak sealer, Kapak Corporation). Each sample was spread evenly, resulting in a thickness below 1 mm in order to ensure complete penetration of e-beam and even distribution of absorbed dose throughout the sample (Jaczynski and Park 2003a, Levanduski and Jaczynski 2008). The samples were stored at -80°C until shipment. The storage time did not exceed one week.

2.3.2 Treatment

Samples were packed and shipped according to an approved institutional protocol in a heavy-duty styrofoam cooler filled with dry ice. Samples were shipped overnight to an e-beam processing facility (Sterigenics International, San Diego, CA, USA). At the e-beam facility, the samples were allowed to equilibrate to 4°C overnight in a refrigerator prior to e-beam processing. The samples at refrigeration temperature (4°C) were subjected to one-sided e-beam with energy fixed at 10 MeV and doses between 0.0-4.0 kGy were applied. The applied e-beam doses were confirmed with film dosimeters (Jaczynski and Park 2003a, Levanduski and Jaczynski 2008). The film dosimeters (FWT-60 series radiochromatic dosimeters, Far West Technology, Inc., Goleta, CA) were attached to the bottom of the Kapak pouches prior to e-beam processing. The absorbed doses were determined following e-beam processing using a spectrophotometer (Cary 100 UV-Vis, Varian, Inc., Palo Alto, CA, USA) with a fixed wavelength at 605 nm. The absorbed doses were used to calculate D-values.

Immediately following the e-beam treatment, samples were frozen, packed, and shipped overnight back to the food microbiology laboratory at West Virginia University (WVU). Upon arrival at WVU, the e-beam processed samples were stored at -80°C until analysis. The storage time did not exceed one week. Preliminary studies (data not shown) determined that the freeze-

thaw cycles used in the experiments did not ($P>0.05$) affect the survival of *E. coli* during e-beam experiments; and therefore, did not confound the results. All of the experiments had control samples that were not exposed to beam (i.e., 0.0 kGy). The control samples received the same treatment as all other samples except for e-beam irradiation; i.e., they were shipped to the e-beam facility in the same heavy-duty styrofoam cooler and stored under the same conditions, but were not irradiated with e-beam. Three separate e-beam experiments ($n = 3$) were conducted.

2.3.3 Bacterial enumeration of *E. coli* survivors

The samples were equilibrated to 4°C overnight in a refrigerator prior to enumeration. Each sample was enumerated by aseptically placing 10 g of the e-beam processed sample using a sterile spatula into a sterile filter stomacher bag (Two-Chamber Filter Bag, Fisher Scientific). An aliquot of 90 ml of diluent (Butterfield phosphate buffer, Hardy Diagnostics, Santa Maria, CA, USA) was aseptically added to the filter stomacher bag and homogenized at medium speed for 2 min in a stomacher (Bag Mixer 400, Interscience, St. Nom, France). Further serial dilutions were aseptically made by taking 10 ml of diluted sample and transferring it into a 90 ml diluent bottle, followed by shaking the bottle to uniformly distribute survivors. Survivors were enumerated on non-selective (Tryptic Soy Agar, TSA) (Becton Dickinson and Company, Sparks, MD, USA) and selective (Petrifilm™ *E. coli*/Coliform Count Plate, 3M™, St. Paul, MN, USA) media using a standard spread-plating technique. An aliquot of 0.1 and 1.0 ml of each serial dilution was pipetted and spread on TSA and 3M™ Petrifilm™ plates, respectively. The TSA and 3M™ Petrifilm™ plates were incubated at 35°C for 24 and 48 h, respectively (AOAC method 991.14 1995). Only plates with 0-150 colonies were counted. All bacterial enumerations were performed in duplicate and the mean values are reported as CFU/g.

Isolation of E. coli survivors for repetitive e-beam processing

Following incubation of the TSA and 3MTM PetrifilmTM plates, colonies of *E. coli* survivors from the highest e-beam dose that resulted in survival were randomly isolated separately from the TSA and 3MTM PetrifilmTM plates. Therefore, two separate isolates of *E. coli* were obtained. One isolate was from TSA plates, while the second isolate was from the 3MTM PetrifilmTM plates. The highest dose applied in the present study was 4 kGy; however, there were no detectable survivor colonies at that dose. Survivor colonies were isolated from the highest dose that resulted in survival of *E. coli*, which was lower than 4 kGy (i.e., the highest dose applied). The isolates from TSA and 3MTM PetrifilmTM plates were separately incubated aerobically in 3.6 ml of sterile TSB at 35°C for 24 h in an incubator/shaker set at 150 rpm. The 3.6 ml aliquots of *E. coli* cultures were separately added to 76 ml of sterile TSB and aerobically incubated at 35°C for 18 h in an incubator/shaker set at 150 rpm. Aseptic technique under the bio-safety cabinet was used for all transfers and handling of *E. coli*. Preliminary studies (data not shown) confirmed that this procedure yielded *E. coli* cultures at stationary phase of growth and approximately 10⁹ CFU/ml.

As described before (“Sample preparation”), the 18-h *E. coli* culture was used as the inoculum for the next sample of fresh ground beef and cycle of e-beam processing. The isolation of *E. coli* survivors following e-beam processing was repeated four times. Therefore, this protocol required four separate shipments to the e-beam processing facility (Sterigenics International). In the first cycle of e-beam processing, the revived *E. coli* DH5 α from Invitrogen Inc. was used. The *E. coli* survivors isolated following the first cycle of e-beam processing were designated as A1 (hereafter called isolate A1), while *E. coli* survivors isolated following the second cycle of e-beam processing using isolate A1 were designated as A2 (hereafter called

isolate A2). Isolates A3 and A4 were obtained accordingly. However, *E. coli* DH5 α is DNA repair deficient rendering this microorganism radio-sensitive (Sommers and Rajkowski 2008). Therefore, in order to acclimatize this microorganism to e-beam, only low doses (0-0.5 kGy) were applied in the first two cycles of e-beam processing. The D-values were not calculated and data are not presented from the first two cycles.

2.3.4 Determining D-values

Following the second cycle of e-beam processing, the counts of *E. coli* survivors (i.e., isolates A2, A3, and A4) enumerated on TSA and 3MTM PetrifilmTM plates were separately plotted on a logarithmic scale as a function of e-beam dose (kGy). Therefore, two separate survivor curves were constructed for isolates A2, A3, and A4. One survivor curve corresponded to *E. coli* survivors enumerated on TSA plates (non-selective media), while the second curve to the survivors on 3MTM PetrifilmTM plates (selective media). The D-value was determined by calculating the negative reciprocal of the slope of the survivor curve (equation 1) (Jaczynski and Park 2003a). D-value is recognized as the radiation dose needed to achieve one log cycle or 90% reduction of the microbial population (Urbain 1986).

$$\log\left(\frac{N}{N_0}\right) = -\frac{1}{D} * t \dots\dots\dots \text{Equation 1}$$

N – concentration of survivors after e-beam dose,

N₀ – initial microbial concentration,

D – D-value, decimal reduction dose,

t – e-beam dose.

2.3.5 Statistics

Five cycles of e-beam processing were conducted, three separate experiments ($n = 3$) per each cycle. The ground beef samples were randomly assigned to e-beam doses in each experiment. All bacterial enumerations were performed in duplicate and the mean values are reported as CFU/g. One-way analysis of variance (ANOVA) was performed to detect significant differences in microbial survival with increasing e-beam dose. The enumeration counts (CFU/g) of *E. coli* survivors for isolates A2, A3, and A4 were log-converted and analyzed by linear regression using MS Office Excel software (Version 2007) in order to determine D-values. The PROC GLM software was used to determine significant differences between mean D-values for *E. coli* enumerated on TSA and 3MTM PetrifilmTM plates within each cycle of e-beam processing (Figures 1-3). The same statistical software was used to determine significant differences between mean D-values for *E. coli* isolates A2, A3, and A4 within each media type (Table I and Figure 4). All statistical analyses were performed using SAS (Version 9) and differences were considered significant when $P < 0.05$ (SAS 2002).

2.4 Results

The average D-values for *E. coli* DH5 α isolates A2, A3, and A4 enumerated on TSA and 3MTM PetrifilmTM plates are presented in Table I. The ANOVA analysis showed that the log-converted counts of *E. coli* survivors for isolates A2, A3, and A4 decreased ($P < 0.05$) significantly as the e-beam dose increased on both TSA and 3MTM PetrifilmTM plates. Therefore, D-values were calculated from the survivor curves as a function of e-beam dose (Figures 1-3). In addition, the GLM analysis proved that the more the microorganisms were subjected to e-

beam, the greater ($P<0.05$) their respective D-values regardless of the media type (non-selective TSA or selective 3MTM PetrifilmTM); and hence, their radio-resistance.

Following the third cycle of e-beam processing, the resultant isolate A2 had the lowest ($P<0.05$) D-values. The D-values were 0.32 ± 0.006 and 0.32 ± 0.002 kGy for A2 survivors enumerated on TSA and 3MTM PetrifilmTM, respectively (Figure 1). However, when these survivors were incubated in ground beef and subjected to the fourth cycle of e-beam processing, the D-values for the resultant isolate A3 increased ($P<0.05$) to 0.39 ± 0.007 and 0.40 ± 0.010 kGy on TSA and 3MTM PetrifilmTM, respectively (Figure 2). The final fifth cycle of e-beam processing yielded increased ($P<0.05$) D-values for isolate A4 at 0.46 ± 0.006 and 0.46 ± 0.020 kGy for survivors enumerated on TSA and 3MTM PetrifilmTM, respectively (Figure 3). *E. coli* DH5 α isolate A2, A3, and A4 survived 1.9, 2.7, and 3.2 kGy (absorbed doses confirmed with dosimetry), respectively. However, the highest e-beam dose applied was 4 kGy and there were no detectable survivors at this dose.

It is important to note that although D-values increased ($P<0.05$) for each subsequent cycle of e-beam processing, the D-values within each cycle were similar ($P>0.05$) for the survivors enumerated on selective and non-selective media. These results indicate that despite its incapability to repair the DNA, *E. coli* DH5 α has the capability to develop increased ($P<0.05$) radio-resistance if repetitively exposed to sub-lethal e-beam. Therefore, besides DNA repair mechanisms; there may also be some other cellular events that lead to the development of increased microbial radio-resistance to ionizing radiation.

2.5 Discussion

The original *E. coli* DH5 α (from Invitrogen Inc.) was radio-sensitive (Sommers and Rajkowski 2008) and had never been exposed to ionizing radiation. Therefore, in order to acclimatize the original *E. coli* DH5 α and isolate A1 had been subjected to low e-beam doses (0-0.5 kGy) in the first two cycles of e-beam processing. Sommers and Rajkowski (2008) subjected *E. coli* DH5 α (from Invitrogen Inc.) in Butterfield's phosphate buffer to gamma radiation using ^{137}Cs . The D-value was 0.051 kGy demonstrating high radio-sensitivity. The D-values for *E. coli* DH5 α isolates A2, A3, and A4 were higher than the D-value for the original *E. coli* DH5 α determined by Sommers and Rajkowski (2008). The higher D-values in the present study were probably caused by the development of increased radio-resistance in *E. coli* DH5 α induced by repetitive processing with e-beam at sub-lethal doses and different food matrices (i.e., ground beef vs. Butterfield's phosphate buffer).

D-values for the pathogenic serotype O157:H7 range depending on several conditions. The D-values reported for *E. coli* O157:H7 in meat products range from 0.19 to 0.63 kGy (Sommers and Boyd 2006a, 2006b, Thayer and Boyd 1993, 2001, Black and Jaczynski 2008, 2007, 2006, Levanduski and Jaczynski 2008). Relatively high D-values between 1.11 and 1.43 kGy have been reported for *E. coli* O157:H7 inoculated in broccoli sprouts (Rajkowski et al. 2003). These published D-values ranging from 0.19 to 1.43 kGy for *E. coli* O157:H7 indicate a profound effect of food matrix on microbial radio-resistance. Microorganisms typically survive irradiation better in food products compared to standard buffers such as Butterfield's phosphate buffer, etc. due to protective effect of food constituents such as proteins and lipids. In addition, microbial cells inoculated into food products and irradiated under stress such as low water activity (A_w) and high ionic strength (IS) typically exhibit increased radio-resistance. *E. coli* also

develops increased acid resistance in foods, which results in “cross-protection” against other stressors including ionizing radiation (Buchanan et al. 1999).

Leyer et al. (1995) demonstrated “cross-protection” and suggested that microbial adaptation to various stressors is influenced by specific outer membrane proteins (“shock proteins”). The expression of “shock proteins” has been associated with enhanced resistance to heat and osmotic stress (i.e., “cross-protection”) (Leyer et al. 1995). Cheville et al. (1996) suggested that *rpoS* gene encodes these protective proteins and/or increases their transcription. Lin et al. (1996) and Yuk and Marshall (2003) confirmed that this gene is involved in the development of increased acid and heat resistance in *E. coli*. The “shock proteins” may also play an important role in the development of the increased radio-resistance of *E. coli* observed in the present study.

To understand the mechanism of microbial radio-resistance Sharan and Nomura (2007) subjected *recA* and *recF* *E. coli* mutant to gamma radiation. They attempted to elucidate the role of *recA* and *recF* proteins in the repair of radiation-induced DNA damage. Their results indicated that there was no difference between the mutant and *E. coli* that was expressing *recA* and *recF* proteins. They concluded that the damage to microbial DNA caused by ionization radiation may require other factors involved in the post-radiation cellular repair. The e-beam-induced radio-resistance of *E. coli* DH5 α in the present study suggests a similar conclusion. To the contrary, in an earlier study, Davis and Sinskey (1973) suggested that the development of radio-resistance was a result of selection that favored mutations leading to the increased radio-resistance and not a result of increased capacity to repair microbial DNA. However, Mount et al. (1975) demonstrated that some mutations increase radio-resistance of *recA* strain of *E. coli*. These authors concluded that although DNA repair is an important mechanism for microbial

survival of ionizing radiation, other cellular mechanisms also play important roles. In the present study the development of increased radio-resistance cannot be attributed to DNA repair because *E. coli* DH5 α carries mutation of the *recA* and *gyrA* genes required for DNA repair. Yet, despite this incapability, *E. coli* DH5 α increased its radio-resistance to e-beam. Thus, other mechanisms, genetic and non-genetic, may also be involved in the development of increased microbial radio-resistance. We intend to investigate the genetic component of increased microbial radio-resistance with micro-arrays and comparative genomic sequences analysis (CGSA). Micro-arrays use RNA and allow rapid gene expression and comparative surveys of large numbers of specimens. In CGSA, DNA (not RNA) of radio-resistant *E. coli* is compared to a sequenced genome allowing identification of changes in the DNA that may have contributed to survival of *E. coli* exposed to e-beam. Preliminary experiments (data not shown) conducted in our laboratory suggest a correlation between up- and down-regulation of some genes and increased microbial radio-resistance to e-beam.

Cell injury normally occurs with ionizing radiation including e-beam. Microorganisms utilize different mechanisms to recover from these injuries under favorable growth conditions (Tesfai et al. 2010). E-beam-induced cell injury likely occurred in *E. coli* DH5 α in the present experiments. However, since *E. coli* DH5 α lacks DNA repair capabilities, the injured cells could not recover. This is why the D-values for isolates A2, A3, and A4 did not ($P>0.05$) differ between survivors enumerated on selective and non-selective media (Figures 1-3).

2.5 Conclusion

Electron beam (e- beam) can efficiently inactivate *E. coli* in fresh food products such as fresh ground beef in a non-thermal manner, similar to other inactivation techniques and environmental stressors, *E. coli* has a capability to develop increased radio-resistance if repetitively processed with e-beam. The potential for increased microbial resistance of foodborne pathogens such as *E. coli* O157:H7 has significant practical implications for the food industry and general public health. The use of genetic analysis such as for example micro-arrays will offer food processors and regulatory agencies a method for rapid detection of strains with increased radio-resistance.

Acknowledgements

This research was funded by the USDA Hatch program (project nr WVA00429). Special thanks to Sterigenics International for allowing us to use e-beam facility. Our appreciation extends to Carl A. Zinn and Richard Vallejo of Sterigenics for invaluable technical expertise with e-beam and Aunchalee Aussanasuwamakul for assistance with statistical analysis.

Declaration of interest: The authors report no conflicts of interest. The authors alone are responsible for the content and writing of the article.

2.6 Appendix C

Table 1. Increased radio-resistance (D-value) of *E. coli* DH5 α in ground beef subjected to e-beam. Data are given as mean $\pm$ standard deviation (n = 3). Mean D-values in rows with different letters indicate significant differences ($P < 0.05$) within media type.

<i>E. coli</i> DH5 α isolate			
Media Type	A2	A3	A4
TSA	0.32 $\pm$ 0.006 c	0.39 $\pm$ 0.007 b	0.46 $\pm$ 0.006 a
3M TM Petrifilm TM	0.32 $\pm$ 0.002 c	0.40 $\pm$ 0.010 b	0.46 $\pm$ 0.020 a

Figure 1: Survivor curves for *E. coli* DH5 α isolate A2 in ground beef subjected to e-beam and enumerated on selective (3M™ Petrifilm™) and non-selective (TSA) media. CHAPTER 3

Understanding radio resistance development of *E.coli DH5α* after exposure to e-beam radiation

Adiam T. Tesfai, William Rittenour, Kristen E. Matak, and Jacek Jaczynski

In preparation for submission to International Journal of Radiation Biology

3.1 Abstract

Electron beam radiation (e- beam) is a non-thermal inactivation method similar to pasteurization that disrupts DNA by introducing cross-links, rendering the organism unable to reproduce its DNA. Unpaired DNA double strand breaks are generally the cause of ionizing radiation induced cell killing, which is reported by increased radio sensitivity of specific repair deficient mutants. *Escherichia coli* DH5 α is a model microorganism that lacks DNA repair capability (carry mutation of the *recA* and *gyrA* genes). The objective of this study was to further understand the role of *recA* and *gyrA* genes in *Escherichia coli* DH5 α that had become resistant to repetitive e- beam radiation and its ability to repair the damage caused by e- beam. Genomic DNA from *Escherichia coli* DH5 α , radio-resistant A2 and A4 were extracted, and DNA fragments of the *gyrA* and *recA* genes containing the mutations were amplified, cloned and sequenced. Sequence comparison of both genes of radio-resistant *Escherichia coli* DH5 α A2 and A4; non-irradiated *Escherichia coli* DH5 α and *Escherichia coli* (K-12) from gene bank database was performed. Our results demonstrate that *Escherichia coli* DH5 α was able to reverse its mutation after sub lethal e- beam irradiations.

3.2 Introduction

Food-borne pathogens cause an estimated 46-million foodborne infections, along with 250,000 hospitalizations and 3,000 deaths in the United States annually and *Escherichia coli* is one of the major food borne microorganisms (Scallan, 2011). *Escherichia coli* lives everywhere in the environment and have the ability to adapt both physically and metabolically to endure harsh environmental conditions as low PH, high temperature, high salinity, antibiotics and irradiation (Bell and Kyriakides, 1998; Tauxe, 2002; Tesfai et al., 2011). Electron beam radiation (e- beam) is a non-thermal inactivation method similar to pasteurization that disrupts DNA by introducing cross-links, rendering the organism unable to reproduce its DNA (EPA- Food Irradiation, 2007). The more complex an organism, the more susceptible its DNA is to e-beam; therefore, an organism as small as *E.coli* can withstand a higher dose than a more evolved organism (Tauxe, 2001). It has been established that *E.coli* has an ability to adapt electron-beam irradiation at levels approaching the recommended dosage of 4.5 KGys (Levanduski and Jaczynski, 2007).

Resistance to extreme environmental stress is a result of several genes working together to allow a cell to withstand the stress and repair any damage that it may incur upon the cell's DNA. Radio-resistance is expressed as the ability to repair DNA double-strand breaks (DSB) generated by ionizing radiation (Cox and Battista, 2005).

In pervious study by Tesfai et al. (2011), we reported radio- resistance development of *Escherichia coli DH5α* that have mutation in *recA* and *gyrA* genes. Radiation resistant cultures of *Escherichia coli DH5α* strain were generated through a series of repeated exposures to e- beam

irradiation followed by growth of survivors. The mutants showed stepwise increase in radio-resistance and it was suggested *Escherichia coli DH5α* that have mutation of *recA* and *gyrA* genes had the ability to recover the DNA damage induced by e- beam despite their repair deficiency. The cause of ionizing radiation induced cell killing is the presence of unpaired DNA double strand breaks which is reported by increased radio sensitivity of repair deficient mutants (Daly et al., 2010).

In order to understand the radio-resistance development of *E.coli* it is important to discuss the DNA repair mechanism employed. *RecA* mediated recombination repair pathway is employed to repair strand break types of damage in *E.coli* (Kuzminov, 1999). SOS response is a response mechanism induced by DNA damage in *Escherichia coli*. The genomic mechanism in SOS response involves *recA* and *lexA* genes among others, which regulate each other by a mixed feedback loop involving transcriptional regulation and protein-protein interaction (Shimoni, 2009). SOS response should be first induced by a signal that simply signifies some change due to DNA damage, which activates a series of reactions. The induction signal activates the *recA* protein protease to cleave and inactivate the *LexA* repressor. The SOS genes are then translated at vastly increased rate until the damage is repaired (Shimoni, 2009). Ghtman et al. (1994) reported that *recA* dependent homologues recombination pathways are involved for radio-resistance development and reconstruction of whole genome in the most radiation resistant microbe, *Deinococcus radiodurans* (Ghtman et al., 1994). Increased radio sensitivity of specific repair deficient mutants such as *recA* has also been reported (Daly et al., 2009).

It is expected that the repair pathways are optimally operational in repair proficient wild type *E.coli* but hampered in *recA* and *gyrA* mutants due to different components of repair pathways being defective in them. Therefore the overall objective of this study was to analyze the role of *recA* and *gyrA* genes of *E.coli DH5α* that had become resistant to stressful stimuli (e- beam radiation), its ability to repair the damage caused by e- beam and thus, understand the genetic mechanisms of e- beam resistance.

3.3 Materials and Methods

3.3.1 Isolation of strains

Escherichia coli DH5 α luxS (bioluminescence S) supE44 (suppressor of amber E44) DlacU169 (deletion lactose U169) [j80 (bacteriophage phi 80) dlacZ (deletion lactose Z) DM15 (deletion M15)] hsdR17 recA1 endA1 (endonuclease A1) gyrA96 thi-1 (thiamine 1) relA1 (relaxed A1) (hereafter called *E. coli*) (Invitrogen Inc., Carlsbad, CA, USA) lyfo-disks were reconstituted by crushing one pellet using a sterile spatula in 0.4 ml of sterile trypticase soy broth (TSB) (Becton Dickinson and Company, Sparks, MD, USA). The content was aseptically transferred to 3.6 ml of sterile TSB and allowed to grow aerobically at 35°C for 24 hrs in an incubator/shaker set at 150 rpm (C24 Incubator/Shaker, New Brunswick Scientific, Edison, NJ, USA). The 4 ml aliquot of the *E. coli* culture was aseptically transferred to 76 ml of sterile TSB and allowed to grow aerobically at 35°C for 24 hrs in the incubator/shaker set at 150 rpm. A 5% inoculum size was then added to a sample of ground beef purchased from local grocery store and thawed overnight to 4 °C. The total mixture was incubated (Isotemp Incubator, Fisher Scientific, Pittsburgh, PA) at 35° C for 24 hrs. Preliminary studies showed that the final microbial count for all samples reached approximately 10⁹ CFU/g. Following incubation, 18 individual samples of approximately 10 g of inoculated beef were separately packaged into bags (Kapak Seal PAK 4” by 6” pouches, Kapak Corporation Minneapolis, MN). Each bagged sample was spread evenly to a width of approximately 1 mm in order to ensure complete penetration of electron beams through out the sample. Double bagging (Kapak seal PAK 6.5” by 8” pouches, Kapak Corporation, Minneapolis, MN) was utilized to ensure that no contamination occurred and samples were stored at -80°C until shipment.

3.3.2 Treatment

Samples were packaged in a Styrofoam cooler containing dry ice to maintain freezing temperature and maintain microbial populations without causing inactivation. Samples were shipped overnight to an e- beam processing facility (Streigencies Intertional San Diego, CA). Once received at the facility, each sample was thawed to 4°C before undergoing treatment. Treatment consisted of exposure of microbes to one-sided e- beam radiation in five increasing doses- 0(control), 0.5 kGy, 1.0 kGy, 1.5 kGy, 2.0 kGy, and 2.5 kGy. Each treatment was performed in triplicate for a total of 18 samples. Immediately following treatment, samples were stored in -80°C freezer. Samples were packed in a Styrofoam cooler with dry ice to maintain freezing temperatures and shipped back to our facility at West Virginia University where they were stored at -80 °C until analysis.

3.3.3 Enumeration

All samples were thawed to 4° C. Each sample was enumerated by placing 10g of the e- beam treated sample using a sterile spatula into a sterile filter stomacher bag (Two- chamber FILTERABAG, Fisher Scientific, Pittsburgh,PA). An aliquot of 90 ml of diluent (Butterfiled phosphate buffer, Hardy Diagnostics, Santa Maria, CA) was aseptically added to the filter stomacher bag and the bag was placed into a stomacher (Bag Mixer 400, interscience,St. Nom, France) for 2 min. Further serial dilutions were aseptically made by taking 10 ml diluted sample and transferring it into a 90 ml diluent bottle, followed by manual shaking to uniformly distribute survivors. An aliquot of 1 ml of each serial dilution was pipetted onto a petrifilm plate (Pertifilm *E.Coli*/Coliform Count Plate, 3M, St. Paul,MN) and spread by a petrifilm spreader. Plates were

incubated at 35°C for 48 hours using AOAC method 991.14. Only plates with 15- 150 colonies were counted. Following enumeration, survivors from the highest e-beam dose were removed at random from the plates using a sterile loop and grown in 10 ml of sterile TSB with shaking (150 rpm). A further inoculum of 2 ml of survivors was then used as an inoculum for the next sample of ground beef and round of radiation. This process was repeated four times for a total of five exposures to increasing e- beam levels. Survivors of the fifth exposure to e- beam were isolated and grown in TSB and became strain A4.

Strains A2 and A4 are the result of a series of electron beam treatments from a radiation resistant population *E. coli* after 2 and 4 cycles of e- beam irradiation, respectively followed by growth as described previous.

The bacterial strains used in this study are shown in Table 1.

3.3.4 Isolation of genomic DNA

E. coli cells of interest were pelleted and re-suspended in 350 µl of tissue lysis buffer (Roche High Pure PCR Template Kit) and transferred to bead beater tube containing 300 µg glass beads. It was Bead beaten for 30 seconds at high speed. The tubes were centrifuged at high speed (~20K x g) and the supernatant collected. After this step genomic DNA was extracted from the samples according to (Roche High Pure PCR Template Kit).

3.3.5 PCR Amplification and purification

All primers were bought from SIGMA- ALDRICH. The PCR cycling parameter (~30 cycles) used were:

PCR Reaction Conditions:

Initial Denaturing	95°C 4 minutes	
Denaturing	50°C 30 seconds	} 30 cycles
Annealing	50°C 30 seconds	
Extension	72°C 1 minute	
Final Extension:	72°C 10 minutes	

All PCR product samples were purified according QIAquick PCR Purification Kit (Qiagen Catalogue # 28104). The purified *recA/gyrA* amplicon was collected and stored at -20°C. The PCR products from non-irradiated *E.coli* (control) founder strain and irradiated radio-resistant strains (A2 and A4) were subjected to 0.9% agarose gel electrophoresis using TAE (Tris-acetate-EDTA).

3.3.6 Cloning, Sequencing

Escherichia coli amplicons were cloned in to pDrive vector using a PCR cloning kit (Qiagen, Valencia, CA, USA) according to the manufacturers instructions. Ligated plasmids were then transformed in to TOP10 chemically competent *Escherichia coli* cells (Invitrogen, Clasbad,CA,USA) according to the manufacturer`s instruction .The transformants were spread

on Luria- Bertani (LB) agar plates containing 100 ug/mL ampicillin and a top layer of X/gal. The plates were then incubated overnight at 37°C. white colonies were selected and cultured in 2mL LB media containing 100ug/ml ampicillin overnight at 37 °C, and plasmid DNA was isolated with a miniprep kit (Qiagen,Valencia,CA,USA) according to the manufacturer`s instructions. Plasmid DNA samples were loaded in to 96 –well plates and sent to GENWIZ (South Plainfield, NJ) for Sanger Sequencing analysis. Sequence comparison of both *recA* and *gyrA* genes of radio-resistant *Escherichia coli* DH5 α A2 and A4, non-irradiated *Escherichia coli* DH5 α , and *Escherichia coli* (K-12) from gene bank database was performed.

3.4 Results and Discussion

As described in the methods section, *gyrA* and *recA* genes were isolated from un-irradiated *E. coli* DH5 α and e-beam treated A2 and A4. Both genes from the isolates were amplified and sequenced for comparison with *E. coli* K12 from gene bank database. The sequence result comparison is shown in Figure -1 for *recA* and Figure -2 for *gyrA*. Figure -1, shows the sequenced part of the *recA* gene of *E. coli* DH5 α , e- beam treated A2 and A4 in comparison with *E. coli* K12; while Figure -2 shows the sequence result of *gyrA* gene.

In *E. Coli* DH5 α , *recA*1 mutation is a single point mutation that replaces glycine 160 of the *recA* polypeptide with an aspartic acid residue (Bryant, 1988) .The result indicates the radio-resistant A2 and A4, which were expected to be similar to the founder strain *E. Coli* DH5 α , acquired back mutations of *recA* gene and were able to reverse to wild type *E. coli* K12 after repetitive e-beam radiation. Single base pair substitution was observed in the sequence result that caused substitution of an amino acid. The summary in Table -3 shows the strains of *E.coli* of

investigation, their phenotypes in terms of e- beam resistance, change in nucleotide position of the *recA* gene corresponding amino acid change in the protein and the position of amino acid change are described. In this case, the changed nucleotide caused a substitution of aspartic acid residue 160 of the *recA* polypeptide with glycine residue (Asp¹⁶⁰ → Gly) in both radio-resistant A2 and A4 strains (Table-3).

Results from our previous experiment indicate *E. Coli DH5α*, which is *recA* and *gyrA* mutant, developed resistance to DNA damage induced by repetitive sub lethal e- beam irradiation (Tesfai et al., 2011). *RecA* in bacteria is highly conserved multifunctional protein that plays a central role in DNA repair and regulation of the SOS response to DNA damage (Roca and Cox, 1990). *recA* production is induced by DNA-damaging treatments such as UV irradiation or nalidixic acid, resulting in up to a 50-fold increase in the amount of the protein as reported by (Kuzminov, 1999). *recA* does not bind to DNA except in the presence of single strand breaks (Kumar, 2004). Thus, e- beam induced single strand breaks resulted in high expression of *recA* gene in *E. Coli DH5α*.

Daly and Minton (1996) stated that cells recovering from the effect of ionizing radiation show biphasic kinetics of double strand break (DSB) repair. The phase I, *recA*-independent, proceeds subsequent to *recA*-dependent mechanisms of DSB repair (Daly and Minton, 1996). In our experiment *E. Coli DH5α* surviving cells were harvested post irradiation and allowed to recover in nutrient rich medium until reaching stationary phase; this population then served as the source of the next culture to be irradiated. As it is shown, they were able to recover from the

DNA damage due to a functional *recA* that was induced by mutation of the DNA repair deficient starting population *E. coli DH5α*.

Our results suggest the involvement of the *recA* gene in DNA damage repair of *E. coli DH5α*. Harris et al. (2012) have also found a similar result, that *recA* mutations make a clear positive contribution to radiation resistance phenotype (Harris et al., 2012). In their experiment, they generated four extremely radiation resistant population of *E. coli* all derived from the same founder strain MG1655 and reported, enhanced recombination DNA repair after extreme genomic degradation plays a major role in radiation resistance in *E. coli* but probably not sole contribution to genome reconstitution (Harris et al., 2012).

The *gyrA* gene is SOS inducible and affects the efficiency of DNA repair and replication (Kornberg and Baker, 1992). Using the primer pair mentioned above, a 365 base pair sequence of *gyrA* gene was also amplified and sequenced (Figure-2). From the gene bank database the *gyrA* gene sequence for *E. coli* K12 was downloaded and compared with the mutant and radio-resistant counterparts. Sequence alteration was also observed with *gyrA* gene for A2 and A4 strains. Sequence result of the strains shows an identical substitution resulting for both radiation treated A2 and A4, where nucleotide sequences no 259 (A) in *E. coli DH5α* founder strain is changed to (G), which is similar to wild type *E. coli* K12 (Table-4). The changed nucleotides caused a substitution of Asn⁸⁷ → Asp in both radio-resistant A2 and A4 strains (Table-4).

Ionizing radiation has a potential to induce mutations, as a number of other physical or chemical antimicrobial agents through DNA damage. Song et al. (2012) have demonstrated

mutation of *E.coli* K12 when irradiated by 10 Kev nitrogen ions for six times. They compared multi- ion irradiated *E.coli* with reference sequence and suggested mutation of genes increased the ability of the *E.coli* genome to resist damage caused by ion- radiation (Song et al., 2012). Base pair substitution was the dominant type of mutation detected genomic alteration after repetitive ionizing irradiation in *E. coli* K-12 (Xie et al., 2004; Harris et al., 2009), which is in agreement to our result.

3.5 Conclusion

Our results demonstrate that the radio resistance phenotype observed in DNA repair deficient *E.coli* DH5 α could have arisen from active DNA repair processes due to back mutation of both genes (*recA* and *gyrA*) after sub lethal e-beam irradiations. Understanding the microbial resistance of food borne microorganisms to irradiation is important and it has implication for determining the efficacy of irradiation in reducing levels of those microorganisms in food.

Acknowledgments

Special thanks to Dr. Brett J. Green and CDC/NIOSH/HELD for allowing us to use their laboratory and valuable discussions. Our appreciation extends to Carl A. Zinn and Richard Vallejo of Sterigenics for technical expertise with e-beam and Tesfalem R. Zere for his assistance with DNA sequence result.

CHAPTER 4

Effect of electron beam on chemical changes of nutrients in infant formula

Adiam Tesfai, Sarah K. Beamer, Kristen E. Matak, Jacek Jaczynski

Submitted to Food Chemistry

4.1 Abstract

Infant milk formula has recently been implicated as a transmission vehicle for an emerging foodborne pathogen, *Enterobacter sakazakii* resulting in high mortality rates. Electron beam (e-beam) efficiently and non-thermally inactivates foodborne pathogens including *E. sakazakii* in infant milk formula. However, the effects of e-beam on chemical changes of nutrients in infant formula have not been determined. Therefore, the objective of this study was to fulfill this gap. Dehydrated infant milk formula was processed with e-beam at 0 (control) to 25 kGy. Amino acid, fatty acid, and mineral profiles (AAP, FAP, and MP, respectively), as well as protein degradation and lipid oxidation were determined. There were no differences ($P>0.05$) in FAP, AAP, and MP. SDS-PAGE electrophoresis qualitatively detected three major protein bands in all samples up to 25 kGy. Densitometry analysis of SDS-PAGE gels confirmed no size degradation ($P>0.05$) as a function of increased e-beam dose. Total-volatile-basic-nitrogen (TVBN) excluded ($P>0.05$) protein degradation due to microbial activity. There was no increase ($P>0.05$) in lipid oxidation as assessed with thiobarbituric-reactive-substances (TBARS) except samples processed at 25 kGy. Dehydrated formula has low water activity, which likely protected nutrients from e-beam-induced chemical changes. This study demonstrates that proteins, lipids, and minerals in infant milk formula are stable when processed with e-beam up to 25 kGy.

Keywords: electron beam; food irradiation; ionizing radiation; nutritional composition; nutritional quality; infant milk formula; fatty acid profile; amino acid profile, lipid oxidation

4.2 Introduction

Infant milk formula has recently been identified as a transfer vehicle for foodborne disease caused by an emerging foodborne pathogen, *Enterobacter sakazakii* (Iversen & Forsythe, 2004; Osaili et al., 2008). Ionizing energy is a well-established non-thermal method aimed at improving microbial safety of a wide range of food products. Ionizing radiation such as electron beam (e-beam), gamma radiation, or X-rays efficiently inactivate foodborne pathogens in food products in a non-thermal manner (Farkas, 1998; Jaczynski & Park, 2004; Black & Jaczynski, 2006; 2007; 2008; Chalise, Hotta, Matak, & Jaczynski, 2007; Arvanitoyannis & Stratakos, 2010; Hvizdzak, Beamer, Jaczynski, & Matak, 2010; Matak, Hvizdzak, Beamer, & Jaczynski, 2010; Tesfai, Beamer, Matak, & Jaczynski, 2011a; 2011b). A non-thermal antimicrobial process is particularly applicable to infant milk formula because it could potentially prevent nutrient losses associated with thermal processing. It could also be applied to infant milk formula in its final stage, after packaging to reduce chances for cross-contamination. It has been shown that ionizing radiation including e-beam inactivates *E. sakazakii* in rehydrated and dehydrated infant milk formula (Osaili et al., 2008; Hong et al., 2008). Lee, Oh, Kim, Yook, & Byun (2006) reported no recovery of *E. sakazakii* in infant milk formula processed with gamma radiation at 5.0 kGy. Lee et al. (2006) also reported that the dose of up to 5.0 kGy had no effect on sensory properties of the dehydrated infant milk formula after rehydration and heating.

Ionizing radiation is used on more than 60 types of foods in more than 40 countries (Arvanitoyannis & Stratakos, 2010; Stefanova, Vasilev, Stefan, & Spassov, 2011). Food irradiation up to 10 kGy is considered unconditionally safe for human consumption (WHO, 1999). Although macronutrients such as carbohydrates, proteins, and fats are generally unaffected by irradiation; lipid oxidation and protein degradation have been demonstrated

(WHO, 1999; 1995; 1994). These effects are dose-dependent and are highly variable for different food products and processing conditions.

Because nutritional quality of infant milk formula is of critical importance, it is expectedly one of the most highly regulated and controlled food products. Although microbial inactivation of *E. sakazakii* in infant milk formula with ionizing radiation including e-beam has been relatively well studied, the chemical changes of nutrients in infant milk formula subjected to ionizing radiation have received insufficient attention. Therefore, the overall objective of the present study was to evaluate effects of e-beam on chemical changes of major nutrients in infant milk formula. This study was focused on determination of amino acid, fatty acid, and mineral profiles, as well as protein degradation (proteolytic degradation with sodium dodecyl sulfate-polyacrylamide gel electrophoresis coupled with densitometry analysis and microbial degradation with total volatile basic nitrogen) and lipid oxidation (thiobarbituric acid reactive substances) in powdered infant milk formula subjected to e-beam up to 25 kGy.

4.3 Materials and methods

4.3.1 Sample preparation

Dehydrated infant milk formula of a national brand was purchased from a chain grocery store. Ionizing radiation may initiate lipid oxidation in food. Since polyunsaturated fatty acids (PUFA) are highly susceptible to lipid oxidation, the formula selected for the present study was fortified with arachidonic (20:4 ω 6) and docosahexaenoic (22:6 ω 3) FAs. Individual samples of approximately 25 g were anaerobically packed (10 x 15 cm Kapak SealPAK pouches, Kapak Corporation, Minneapolis, MN). Prior to e-beam processing, the infant milk formula was evenly spread in each pouch, resulting in a thickness below 3 mm. This thickness insured complete penetration of e-beam and even distribution of absorbed dose throughout the sample (Jaczynski

& Park, 2003a; 2003b). The samples were stored at -80°C until shipment. The storage time did not exceed one week.

4.3.2 Electron beam processing

Samples were shipped overnight to the e-beam facility (Sterigenics International, San Diego, CA) in a heavy-duty styrofoam cooler filled with dry ice. At the e-beam facility, the samples were allowed to equilibrate to 4°C overnight in a refrigerator prior to e-beam processing. The samples at refrigeration temperature (4°C) were subjected to the following target doses 0 (control), 5, 10, 15, 20, and 25 kGy of one-sided e-beam with energy fixed at 10 MeV. The target doses were confirmed with film dosimetry (Jaczynski & Park, 2003a; 2003b). Film dosimeters (FWT-60 series radiochromatic dosimeters, Far West Technology, Inc., Goleta, CA) were attached to the bottom of the Kapak pouches prior to e-beam processing. The absorbed doses were determined with a spectrophotometer (Cary 100 UV-Vis, Varian, Inc., Palo Alto, CA) at 605 nm. The absorbed doses were 5.7, 11.6, 18.0, 22.9, and 28.7 kGy, respectively.

Immediately following e-beam processing, samples were frozen, packed with dry ice, and shipped overnight back to the food science laboratory at West Virginia University for analysis. Upon arrival, the e-beam processed samples were stored at -80°C until analysis. The storage time did not exceed one month.

4.3.3 Amino acid profile (AAP)

The infant milk formula samples processed with e-beam were analyzed for full amino acid profile (AAP) according to the AOAC (1995) method 982.30 E (a, b, c). The e-beam processed samples were subjected to the following three types of hydrolysis: acid hydrolysis with 3 mol L⁻¹ HCl at 110°C for 24 h, performic acid oxidation at 0-5°C overnight followed by acid hydrolysis (3 mol L⁻¹ HCl at 110°C for 24 h), and alkaline hydrolysis with fresh 2.1 mol L⁻¹

NaOH at 110°C for 22 h. Following hydrolysis, AAs were quantified using the Beckman Amino Acid Analyzer (model 6300, Beckman Coulter, Inc., Fullerton, CA) employing sodium citrate buffers as step gradients with the cation exchange post-column ninhydrin derivatization method (Chen, Tou, & Jaczynski, 2008; Taskaya, Chen, Beamer, Tou, & Jaczynski, 2009; Kassis, Beamer, Matak, Tou, & Jaczynski, 2010). Although full AAP was determined, taurine, lanthionine, ornithine, and hydroxylysine were either not detected or detected at negligible levels; and therefore, are not reported. However, concentrations of these AAs were included in calculations of the total AAs. The data are reported as mean values ($\pm$ standard deviation) of at least three replicates. The mean values are expressed as g of AA per 100 g of e-beam processed sample.

4.3.4 *Total volatile basic nitrogen (TVBN)*

Protein degradation due to potential microbial activity was determined with total volatile basic nitrogen (TVBN) assay (Goulas & Kontaminas, 2005; Tahergorabi, Beamer, Matak, & Jaczynski, 2012c). To determine TVBN, 5 g of a sample processed with e-beam was mixed with 50 ml of distilled deionized water (dd H₂O). One drop of silicone and 2 g of magnesium oxide were added to prevent foaming. The mixture was distilled in a Micro-Kjeldahl unit and the distillate was titrated with 0.05 mol L⁻¹ HCl. The TVBN values are reported as mean values ($\pm$ standard deviation) of at least three replicates. The mean values are expressed as mg of nitrogen per 100 g of e-beam processed sample.

4.3.5 Sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) and densitometry analysis

Proteolytic degradation of protein and/or protein polymerization was determined by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) in conjunction with densitometry analysis. SDS-PAGE is considered a qualitative analysis, while densitometry is quantitative. 0.4 g of a sample processed with e-beam was dissolved in 40 ml of dd H₂O. The same protein concentration between formula samples processed at different e-beam doses was verified with Lowry assay (Lowry, Rosenbrough, Farr, & Randall, 1951). An aliquot of 10 µl of the dissolved sample was mixed with 10 µl of Laemmli sample buffer (Bio-Rad, Richmond, CA) and heated at 90°C for 5 min (Jaczynski & Park, 2004). Aliquots of 20 µl per well were used for SDS-PAGE.

Ready-to-use 4-20% gradient gel (Bio-Rad, Richmond, CA) was used for SDS-PAGE. SDS-PAGE was performed under denaturing conditions and constant current of 80 V (Jaczynski & Park, 2004). The Precision Plus Protein™ Kaleidoscope™ protein standards (10-250 kDa) (Bio-Rad, Richmond, CA) were added to the SDS-PAGE along with the e-beam processed samples. The electrophoretic protein patterns were stained with EZ-Run protein staining solution (Bio-Rad, Richmond, CA), followed by destaining with dd H₂O.

The SDS-PAGE gel images were captured using a digital camera interfaced with a PC (Fluorchem 8000, Alpha Innotech Corp., San Leandro, CA) using transilluminating white light (Alpha Innotech Corp., San Leandro, CA) (Gigliotti, Davenport, Beamer, Tou, & Jaczynski, 2011; Kassis, Gigliotti, Beamer, Tou, & Jaczynski, 2012). The optical density of protein bands from SDS-PAGE images was analyzed using the Fluorchem software (version 1.0, Alpha Innotech Corp., San Leandro, CA). The densitometry data are reported as mean values ($\pm$

standard deviation) of at least three replicates. The mean values are expressed as integrated pixel density of a protein fraction. A sample representative SDS-PAGE gel image is also reported.

4.3.6 Fatty acid profile (FAP)

The infant milk formula samples processed with e-beam were analyzed for fatty acid profile (FAP). The e-beam processed samples were subjected to lipid extraction with acid hydrolysis into ether followed by their methylation to fatty acid methyl esters (FAMES) (Chen, Nguyen, Semmens, Beamer, & Jaczynski, 2007; Pietrowski, Tahergorabi, Matak, Tou, & Jaczynski, 2011). The FAMES were quantitatively measured using a capillary gas-liquid chromatograph (GLC) (Model 7890A equipped with a 7683B series injector, Agilent Technologies, Santa Clara, CA) against an internal standard (C19: 1). Helium was used as carrier gas at 0.75 ml/min flow rate and a 200:1 as split ratio. The initial temperature of 100°C was held for 4 min and then increased to the final temperature of 240°C at a rate of 3°C/min. The final temperature was held for 15 min. The injector and detector temperatures were 225 and 285°C, respectively. The data are reported as mean values ($\pm$ standard deviation) of at least three replicates. The mean values are expressed as percent of a FA in total FAs.

4.3.7 Thiobarbituric acid reactive substances (TBARS)

Lipid oxidation in infant milk formula processed with e-beam was determined with thiobarbituric acid reactive substances (TBARS) assay of malondialdehyde (MDA) as previously described (Yu & Sinnhuber, 1957; Tahergorabi, Beamer, Matak, & Jaczynski, 2012a). The absorbance was measured at 535 nm using an UV/Vis spectrophotometer (model DU530, Beckman Instruments, Fullerton, CA). The TBARS values were calculated using molar absorptivity of MDA ($156,000 \text{ M}^{-1} \text{ cm}^{-1}$) at 535 nm. The TBARS values are reported as mean

values ($\pm$ standard deviation) of at least three replicates. The mean values are expressed as mg of MDA per kg of e-beam processed sample.

4.3.8 Mineral Profile (MP)

The infant milk formula samples processed with e-beam were analyzed for mineral profile (MP). All glassware was washed overnight in a solution of 0.3 mol L⁻¹ HCl in dd H₂O prior to use. Ashed samples were dissolved in 2 mL of 7.7 mol L⁻¹ nitric acid. The acidified samples were neutralized and filtered through Whatman number 1 paper (Whatman International Ltd., Maidstone, United Kingdom). Samples were diluted to volume with dd H₂O in a 50 mL volumetric flask. Mineral (Ca, P, Mg, Fe, Zn, Na, and K) contents were determined using inductively coupled plasma optical emission spectrometry (model P400, Perkin Elmer, Shelton, CN) (Tahergorabi, Beamer, Matak, & Jaczynski, 2012b; 2012d). The mineral contents are reported as mean values ($\pm$ standard deviation) of at least three replicates. The mean values are expressed as mg per 100 g of e-beam processed sample.

4.3.9 Statistics

All experiments were independently triplicated ($n = 3$). In each triplicate at least three measurement were performed. Data were subjected to one-way analysis of variance (ANOVA). A significant difference was determined at 0.05 probability level and differences between treatments were tested using Fisher's Least Significant Difference (LSD) test (Freud & Wilson, 1997). All statistical analyses of data were performed using SAS (SAS, 2002). The data are reported as mean values $\pm$ standard deviation (SD).

4.4 Results and discussion

4.4.1 Amino acid profile (AAP) and total volatile basic nitrogen (TVBN)

The amino acid profile (AAP) results shown in Table 1 indicated no difference ($p > 0.05$) in amino acid composition as a function of increasing e-beam dose up to 25 kGy when compared to the control (0 kGy). The sulfur-containing AAs, methionine and cysteine are the most radiosensitive AAs (Stewart, 2001). From a human nutrition stand point; methionine is considered a limiting essential AA. Because methionine is the most radiosensitive AA with critical nutritional importance to humans, it should be considered an indicator of radiation-induced AA degradation. As shown in Table 1, neither of the two most radiosensitive AAs was affected ($P > 0.05$) by e-beam in the present study. In fact, the content of all AAs remained unchanged ($P > 0.05$) as the e-beam dose increased to 25 kGy.

El-Rawas et al. (2011) also reported no changes in AAP and crude protein content of peanut butter processed with e-beam up to 28 kGy. However, Matloubi et al. (2004) observed very slight changes in AAP of baby food processed with gamma radiation (^{60}Co) up to 50 kGy at room temperature and in the presence of oxygen. The content of some AAs was slightly increased, while others decreased. Nevertheless, the authors concluded that ionizing radiation generally did not cause chemical changes in AAs. The infant milk formula used in the present study was a dehydrated product with water activity (A_w) of 0.45. Peanut butter also has a comparably low A_w at approximately 0.35 (Burnett, Gehm, Weissinger, & Beuchat, 2000). Low A_w indicates unavailability of water for chemical reactions such as water radiolysis that produces free radicals. The free radicals may cause AA degradation. Ionizing radiation including e-beam typically initiates water radiolysis in foods with high A_w . Therefore, low A_w reduces potential radiation-induced AA degradation. This is likely a main factor that contributed to the lack of

changes in AAP reported by El-Rawas et al. (2011) and in the present study. Dehydrated milk powders have been reported to be more resistant to radiation-induced chemical changes (Diehl, 1983). Matloubi et al. (2004) irradiated baby food up to 50 kGy unlike up to 25 and 28 kGy in the present study and by El-Rawas et al. (2011), respectively. Radiation-induced chemical changes are dose-dependent; and thus, the higher doses applied by Matloubi et al. (2004) could have resulted in the observed slight differences. Unlike gamma radiation, e-beam delivers target dose at a much greater rate (e-beam – 10^3 - 10^5 Gy/sec; gamma – 0.01-1 Gy/sec); and thus, e-beam processing time is much shorter. The shorter time and greater dose rate of e-beam have also been attributed to less change in e-beam processed food when compared to gamma irradiation. The infant milk formula in the present study was anaerobically packed and processed with e-beam at refrigeration temperature. In addition to the low A_w , the low temperature and relative absence of oxygen likely contributed to the lack of differences in AAP reported in the present study.

The total volatile basic nitrogen (TVBN) indicates protein degradation as a result the release of N-containing volatile compounds from the protein due to microbial activity/spoilage (Gram & Huss, 1996). The analysis of TVBN for infant milk formula processed with e-beam at 0-25 kGy showed no difference ($p > 0.05$) in protein degradation (Table 1). TVBN content of 30 mg N/100 g is considered as acceptability limit (Sikorski, Kolakowska, & Burt, 1990). All of the infant milk formula samples in the present study had TVBN below 13 mg N/100. This indicates that, the protein in the infant milk formula used in the present study was not degraded by microorganisms including the control (0 kGy). Therefore, the only possibility of protein degradation was a chemical degradation mediated by e-beam radiation. The AAP in combination with TVBN showed no changes in AA composition and protein degradation,

respectively in infant milk formula processed with e-beam up to 25 kGy.

4.4.2 Sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) and densitometry analysis

Fig. 1 shows SDS-PAGE and densitometry analysis. The SDS-PAGE image included in Fig. 1 is a representative sample image, while the densitometry graph in Fig. 1 is a quantification ($n = 3$) of protein bands detected in infant milk formula in the present study. The SDS-PAGE electrophoresis detected three major protein bands. By using protein standards of known molecular weight (M_w), the detected protein bands were identified as two isomers of casein with M_w of approximately 30-32 kDa and lactalbumin with M_w of approximately 14 kDa. The number of protein bands in the gel did not change with increasing e-beam dose. The increased number of protein bands of smaller M_w with increasing e-beam dose would indicate a potential size degradation of the original protein fractions present in the un-processed infant milk formula (i.e., control – 0 kGy).

Although SDS-PAGE showed no qualitative changes in protein (i.e., the number of protein bands did not increase with increasing e-beam dose), SDS-PAGE is not a quantitative analysis. This is why to quantify potential size degradation of protein as a function of increasing e-beam dose; the SDS-PAGE images were analyzed with densitometry. The densitometry analysis of SDS-PAGE gel images showed no difference ($p > 0.05$) in integrated pixel density of the detected protein fractions. The differences in pixel density of the detected protein fractions would indicate differences in concentration of these fractions. Since protein at the same concentration was injected into each well of the SDS-PAGE cell corresponding to different e-beam doses and there were no differences in pixel density, it can be concluded that the M_w of the

detected fractions remained unchanged regardless of e-beam dose up to 25 kGy. Thus, the degradation of protein size in infant milk formula processed with e-beam did not occur.

It has been demonstrated that ionizing radiation of food can induce protein radiolysis by breaking peptide bond, leading to the formation of free AAs and some decomposition products such as protein fractions with smaller M_w and individual peptides (Erkan & Ozden, 2007). El-Rawas et al. (2011) reported no differences ($P > 0.05$) in band pixel density; and hence, protein degradation in peanut butter processed with e-beam at 3.2 and 7.0 kGy when compared to control (0 kGy). In contrast, Jaczynski & Park (2004) showed size degradation of myosin heavy chain and actin in surimi when processed with e-beam at 10 and 25 kGy, although 1-8 kGy did not cause the degradation. However, surimi as a fresh seafood product derived from fish muscle has high A_w as opposed to peanut butter and infant milk formula. In addition, surimi was irradiated at room temperature and under aerobic conditions. These differences likely explain the differences in protein size degradation reported by Jaczynski & Park (2004).

4.4.3 Fatty acid profile (FAP)

Fats are among the least stable food components. They are susceptible to radiation-induced autoxidation, which may lead to the development of rancidity in addition to reduced nutritional quality including the loss of essential fatty acids (Giroux, 1998; Mexis & Kontominas, 2009; Cheng et al., 2011). Unsaturated fatty acids (FAs), especially long chain polyunsaturated FAs such as ω -3 FAs (linolenic, ALA, 18:3 ω 3; eicosapentaenoic, EPA, 20:5 ω 3; and docosahexaenoic, DHA, 22:6 ω 3) and ω -6 FAs (linoleic, LA, 18:2 ω 6 and arachidonic, AA, 20:4 ω 6) are more prone to oxidation than saturated FAs. Yet, these specific ω -3 and ω -6 FAs are critical in human nutrition, particularly for infants. This is why although full FAP was

determined; Table 2 presents only those nutritionally critical ω -3 and ω -6 FAs along with major saturated FAs. No differences ($P > 0.05$) were detected for any of the FAs in infant milk formula processed with e-beam up to 25 kGy. As a consequence, there were no differences ($P > 0.05$) in the composition of total ω -3, ω -6, saturated FAs, and unsaturated FAs (Fig. 2) or the ratio of total ω -6/total ω -3 and unsaturated FAs/saturated FAs (Table 2).

The results of the present study are in agreement with Alfaia et al. (2007) who reported that gamma irradiation of vacuum packaged frozen lamb meat at 7 kGy did not change FAP or total lipid content. Freezing food causes immobilization of water molecules; and therefore, water becomes less available. As such, A_w of frozen food is lower than their unfrozen counterparts. When foods with high A_w are processed with ionizing radiation, high concentrations of hydroxyl radicals are generated from water radiolysis. These radicals may initiate lipid oxidation, leading to changes in FA composition of irradiated food. Such reactions proceed at significantly slower rates in dehydrated food with low A_w (Brito, Villavicencio, & Mancini-filho, 2002; Mexis & Kontominas, 2009). The infant milk formula used in the present study had low A_w and it was very likely a reason why changes in FA composition similar to AA composition were not detected.

4.4.4 Thiobarbituric acid reactive substances (TBARS)

Thiobarbituric acid reactive substances (TBARS) assay was used to measure the effect of e-beam on oxidation of lipids in infant milk formula. Results showed dose-dependent and gradual, yet insignificantly increasing trend ($P > 0.05$) for TBARS values up to 20 kGy (Fig. 3). However, e-beam at 25 kGy induced lipid oxidation and greater ($P < 0.05$) amount of secondary products of lipid oxidation (i.e., malondialdehyde – MDA) was detected with TBARS assay. It needs to be noted that due to inherent variations of TBARS assay, the TBARS value for samples

processed with e-beam at 25 kGy was only higher ($P < 0.05$) than the control (0 kGy) and 5 kGy samples, but it was not ($P > 0.05$) greater than the 10, 15, and 20 kGy samples. The TBARS values increased from 2.48 ± 0.53 mg MDA/kg for the control samples to 6.84 ± 2.42 for infant milk formula processed with e-beam at 25 kGy.

The results from the present study are in general agreement with previously reported studies showing that ionizing radiation may induce lipid oxidation. However, the extent of lipid oxidation is dose-dependent and it also depends on intrinsic factors such as specific food matrix (A_w , added antioxidants and oxygen scavengers) and its lipid composition, as well as extrinsic factors associated with processing conditions, especially oxygen availability (i.e., anaerobic vs. aerobic packaging) and sample temperature during irradiation (Stefanova et al., 2011). El-Rawas et al. (2012) showed that lipid oxidation occurred in peanut butter processed with e-beam at doses over 7 kGy; while Sohn et al. (2009) reported that TBARS values of ground beef irradiated with 5 and 10 kGy were higher than the non-irradiated control. In the present study, all of the factors disfavored radiation-induced lipid oxidation and this is likely why TBARS values did not ($P > 0.05$) increase until 25 kGy.

4.4.5 Mineral profile (MP)

Mineral profile (MP) results are shown in Table 4. The minerals studied in the present study were not ($P > 0.05$) altered by e-beam up to 25 kGy. No difference ($P > 0.05$) was detected in Ca, P, Mg, Fe, Zn, Na, and K content of infant milk formula processed with e-beam up to 25 kGy when compared to the control (0 kGy). However, Bhat & Sridhar (2008) reported changes ($P < 0.05$) in mineral composition of tropical legumes processed with e-beam. Although Ca increased ($P < 0.05$) at 10 kGy, Zn and K were reduced ($P < 0.05$) at 5 and 10 kGy, respectively. As mentioned above in the TBARS section, the effects of ionizing radiation such

as e-beam on food nutritional quality are dose-dependent and depend on several intrinsic and extrinsic factors (Stefanova et al., 2011).

4.5 Conclusions

Many studies have demonstrated that nutrients are not largely affected by ionization radiation even at high doses exceeding 10 kGy. The present study also shows that proteins, fats, and minerals in dehydrated infant milk formula are stable when processed with electron beam (e-beam) up to 25 kGy. Infant milk formula has recently been implicated as a transmission vehicle for an emerging foodborne pathogen, *Enterobacter sakazakii*, resulting in relatively high mortality rates. As a non-thermal antimicrobial strategy, e-beam processing did not affect nutritional attributes of dehydrated infant milk formula tested in the present study.

Acknowledgment

Special thanks to Sterigenics International for allowing us to use e-beam facility. Our appreciation extends to Carl A. Zinn and Richard Vallejo of Sterigenics for invaluable technical expertise with e-beam.

4.6 Appendix E

Table 1: Amino Acid Profile (AAP) of powdered infant formula processed with e-beam at 0, 5, 10, 15, 20, and 25 kGy. Data are given as mean values $\pm$ standard deviation ($n = 3$). The mean values are expressed as g of AA per 100 g of e-beam processed sample. Different letters indicate significant differences (Fisher's Least Significant Difference, $P < 0.05$) between mean values within the same row. The lack of letters indicates lack of differences. TVBN – Total Volatile Basic Nitrogen (TVBN). The mean values for TVBN are expressed as mg of nitrogen per 100 g of e-beam processed sample.

Figure 1:

A sample representative SDS-PAGE gel image (top) and densitometry analysis (bottom) of protein in powdered infant formula processed with e-beam at 0, 5, 10, 15, 20, and 25 kGy. The densitometry data are reported as mean values $\pm$ standard deviation (SD) ($n = 3$). The mean values are expressed as integrated pixel density of a protein. The small bars of the top of data bars indicate SD. Different letters on the top of SD bars indicate significant differences between mean values (Fisher's Least Significant Difference, $P < 0.05$) within the same protein type. However, the lack of letters indicates lack of differences.

Figure 2:

Major groups of fatty acids (FAs) in powdered infant formula processed with e-beam at 0, 5, 10, 15, 20, and 25 kGy. Data are given as mean values $\pm$ standard deviation (SD) ($n = 3$). The mean values are expressed as percent of a FA group in total FAs. The small bars of the top of data bars indicate SD. Different letters on the top of SD bars indicate significant differences between mean values (Fisher's Least Significant Difference, $P < 0.05$) within the same FA group. However, the lack of letters indicates lack of differences.

Figure 3:

TBARS (thiobarbituric acid reactive substances) values of powdered infant formula processed with e-beam at 0, 5, 10, 15, 20, and 25 kGy. Data are given as mean values $\pm$ standard deviation (SD) ($n = 3$). The mean values are expressed as mg of MDA (malondialdehyde) per kg of e-beam processed sample. The small bars of the top of data bars indicate SD. Different letters on the top of SD bars indicate significant differences between mean values (Fisher's Least Significant Difference, $P < 0.05$).

Dissertation Summary and Implications

Electron beam radiation has been receiving increased attention as a non-thermal food processing. Our study demonstrated e-beam efficiently inactivate *S. Typhimurium* in raw egg and there was no growth after 3 KGy; however, similar to other inactivation techniques and factors affecting microbial growth, *S. Typhimurium* develops increased radio-resistance if repetitively processed with e-beam at sub-lethal doses. The D_{10} -values for *S. Typhimurium* enumerated on non-selective media (TSA) were greater ($P < 0.05$) than on selective (XLD) media for all five cycles of e-beam irradiation, indicating sub-lethal injury followed by cellular repair and recovery are important aspects of microbial inactivation with e-beam. E-beam as a non-thermal process can be used as an alternative method to efficiently control *S. Typhimurium* in egg.

Our results demonstrate *E. coli* DH5 α increases radio-resistance to e-beam as a result of repetitive exposure to sub-lethal doses despite its DNA repair deficiency. The radio resistance phenotype observed in DNA repair deficient *E. coli* DH5 α could be arisen from active DNA repair process due to back mutation of both genes (*recA* and *gyrA*) after sub lethal e-beam irradiations. Based on our result we can conclude, DNA repair mechanism is important in radio-resistance development in *E. coli*. Understanding the microbial resistance of food borne microorganisms to irradiation is important and it has implication for determining the efficacy of irradiation in reducing levels of those microorganisms in food.

From the result of our last study, e- beam radiation doesn't affect the nutritional content of infant formula thus it can be applicable in processing infant formula. Our result shows proteins, fats, and minerals in dehydrated infant milk formula are stable when processed with electron beam (e-beam) up to 25 kGy. This application has not yet been exploited and has the potential to enhance the safety of infant milk formula. Losses of vitamins can be caused by e- beam radiation, which is not covered in our experiment, thus it is recommended to study the effect of e-beam on vitamins in infant formula.

Studying the inactivation and radio-resistance development of foodborne microorganisms is important to scientists, food processing industry and regulatory agencies for adaptation of new processing technology, making decision and formulation of law and policies.
